Power meters are in wide use and directly measure power by detecting the amount of heat it produces.

Technically, RF energy passing a point/plane during a unit
of time is RF power (joules/sec). We can't have one without
the other.

OK, I'm a little confused. Well, maybe more than a little.

Starting with energy as the "ability to do work" and power as the rate at which energy is "transformed" into work, things quickly get muddy.

Energy passing through an imaginary surface (or point or plane) would not actually do any work in passing through, and in fact would retain its full potential to do work after having passed through.

What then is power density? Is it the amount of work that the energy passing through a unit area of the surface "could have done" had it been actually and fully "captured" at that surface? There is no real power at that surface, is there?

While power (and work) absolutely require energy, it strikes me as metaphysical whether all energy ultimately does do work and produce power. I don't think physics requires that, and it seems that lot of radiated energy is not obviously being transformed into work. So is energy without power really impossible, Cecil?

Been away from this for a longer bit than I'm comfortable mentioning.

Power is the rate at which energy is transferred or used. Period.

> Energy passing through an imaginary surface (or point or plane) would
> not actually do any work in passing through, and in fact would retain
> its full potential to do work after having passed through.

Yes.

> What then is power density? Is it the amount of work that the energy
> passing through a unit area of the surface "could have done" had it been
> actually and fully "captured" at that surface?

No. Power is not an "amount of work", nor is power density. Power is the rate at which power is being transferred, so it can tell you only the rate at which work can be done, not the amount. The rate at which energy is being passed through a given cross sectional area of a surface is the power density. If you integrate the power going across the boundary for some period of time, you then know the amount of energy which has passed, and therefore the amount of work which can be done.

There is no real power at
> that surface, is there?

There is real energy passing that surface, and the rate at which it's passing is the power at that surface. So yes, there is.

> While power (and work) absolutely require energy, it strikes me as

Cecil loves metaphysical arguments, so this is an ideal question for him.

> Been away from this for a longer bit than I'm comfortable mentioning.

Try finding a basic physics textbook at your local library. Most high school level texts should cover the topic adequately. For a more mathematical and quantitative treatment, a freshman level college text would be fine. A couple of the more popular ones are Resnick & Halliday, and Weidner & Sells. In the older editions of both, at least, electrical phenomena are covered in the second volume. However, power, work, and

energy aren't restricted to electricity so are covered in general terms in the first volume.

Very interesting Roy. It makes me feel a lot better about eliminating my fixation with silver plating inductors. I was aware that there are different classes of copper oxides, but have only ever seen green and black oxides. I did find some data on oxide conductivity, but cannot locate it now. In fact you may have even been the source for this information.

Concerning the Fowler paper; Rudy Severn also published an article in QEX, for Nov/Dec 2000, where he briefly discusses the math. I believe there are also errors in his math, but have not looked at it for a year or so.

Well for those of us who don't get around so well, it was nice to have a
product name to ask for.
Home Depot had an even smaller tube 1/2 oz and I got some steel wool to
buff things up first.
both less than $6. I probably would have been an hour finding that tiny
tube hanging in the store.
With more days behind me now than ahead.... and hoping my next antennas
will be new ones. It should last me till my end. Kinda like buying a tube
of water pipe compound
once you use it once the rest hangs around forever. LOL
Thanks for brand name to ask for. Saved lots of steps I can't spare these
days.

chuck wrote:
> So is energy without power really impossible, Cecil?

Roy has already answered the basic question from an engineering viewpoint. Physicists often consider "power" to have a different definition than the engineering definition.

From the IEEE Dictionary: "power - The rate of generating, transferring, or using energy." (agrees with Roy)

From "University Physics" by Young and Freedman: "power is the time rate at which work is done." i.e. only the "using energy" portion of the engineering definition.

A certain physicist I know will argue that no work is being done in a lossless transmission line so there is no power there. He will say the existence of 100 watts at 1000 points along the line means there must be 100,000 watts in the line. He will say that a Bird wattmeter doesn't measure watts. He will say that a power generating plant doesn't generate power and a transmission line doesn't transfer power. He will also say that reflected power doesn't exist because it is not doing any work. He will say that for an EM wave in free space, ExH has the dimensions of watts but it isn't power because no work is being done.

As Roy indicated, engineers have a wider definition of "power". Energy without power is certainly possible, e.g. a DC battery with zero current. However, for a constant steady-state power level associated with an EM wave, energy and power are inseparable.

I like to use a one-second long lossless transmission line in some of my examples because it is impossible to hide the joules. A one-second long line with 200 watts forward power and 100 watts reflected power contains 300 joules that have been generated but have not reached the load. Since EM wave energy cannot stand still (or slosh around side to side) it is only logical to assume that 200 of those joules are in the forward wave and 100 of those joules are in the reflected wave both traveling at the speed of light.

Marine supply stores sell bronze wool. I think the boaters use it for
cleaning brass fittings, presumably without scratching them. (I used it as
EMI packing for some leaky old pull-boxes.)

It may be close enough to copper wool to function the same.

Quoth:
On 80m and 40m I have used a 33' vertical in the bed of my truck fed
with an "L" network and had good results. Leads me to believe that the

33' would work well with a modest ground system.

For 80 Meters:I have had decent results in end feeding (connect the
conductor and shield together to make a single conductor) a 40 meter
dipole xmission line into a grounded Pi network (your average MFJ
tuner); what you have is an end fed long wire with a really big
capacitance hat. Works best if the xmission line is 1/4 wave (i.e. 66
ft), but it's not critical. Also, the better the RF ground the better
the efficiency. And hey, it even works to some extent on 160, as long
as you keep the power output in check.

>What then is power density?

The full name is power *flux* density, implying the rate at which energy
flows through unit area of a defined reference plane. SI units are
watts per square metre.

> Is it the amount of work that the energy passing through a unit area
>of the surface "could have done" had it been actually and fully
>"captured" at that surface?

Yes, that is the implication - except that it's the *rate* of energy
capture, ie the amount that could be captured from unit area in unit
time.

This is only a concept, because it isn't physically possible to
intercept the power flux through unit area of an EM wavefront - your
wave-catcher would disturb the wavefront around its edges, and the
shadow behind it would be filled in by diffraction. However, very
similar concepts apply to power flux in a transmission line - and in
that case you really *could* capture the exact steady-state power flux
at any point, by cutting the line and substituting a dummy load of the
correct impedance.

>There is no real power at that surface, is there?
>
That rather depends on your personal definitions of the words "real",
"at" and possibly "is" :-) I think you'd caught it correctly in the
previous paragraph... but if you squeeze too hard, the waves will slip
through your fingers.

1407. Receiving VMS (Vessel Monitoring Signals) from Inmarsat-C

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-14 12:12:28 UTC
From: Michael <ccc73571@vip.cybercity.dk>
Message-ID: <UOjIf.43$zu4.18@news.get2net.dk>
Source record: 64468

I have been playing around with receiving AIS (Automatic Identification System) signals. AIS is used on ships, it is used to send information about your position, etc via VHF to the surrounding ships. But know this started to get a bit boring. So know I wan to try to se if it is possibly to receive the VMS signals from Inmarsat-C. The VMS system is manly used on fishing vessels. On the ship there is a box with a gps and satellite tranciver. The position information is send each hour, to a land earth station, were it is distributed to the different authorities.

The first thing is to receive the signals. But also to decrypt the data can be complicated.

Any help or advices are welcome. Also if you have some good links to people ho have been dealing with projects like this, could be useful.

Cheers Michael

1412. What's the best way to measure radiated power from an antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-14 15:16:58 UTC
From: MRW <mr.whatever@gmail.com>
Message-ID: <1139930218.609008.164890@g43g2000cwa.googlegroups.com>
Source record: 64473

Happy Valentine's Day!

In terms of high powered transmitter (at least 500W), what is the best way to measure the output power from an antenna? I had pictured an in-line power sensor between the matching network and the antenna, but then at 500W I don't think I'll get close to the transmitter.

My friend actually proposed of finding out how long it will cook an egg if exposed to a certain output power and used that as a reference to approximate whether the power output. But then again I think you'd initially need to cook a couple of eggs in a controlled environment before a nice curve can be derived.

Also, during our engineering expo, a power company showcased their infrared tools to detect whether or not a power line is overloaded, shorted, or working normally. I was wondering if there is a similar tool used on antennas.

Thanks!

Source record: 64475

I think the differences in this discussion go back to very fundamental definitions of power and energy (and power flux, which might not be the same as power). One set of terminology came from classical Thermodynamics and the other set from more general principles. More fun may be had dealing with the Second Law (which arrived from two very different viewpoints) and, for example, quantum effects in the same discussion. The discussion can quickly hinge on precise meanings of common words, such as "power."

Mixing terminology produces such wonderful concepts as measuring 100 watts flowing at 100 points in a transmission line and concluding that we have found 10,000 watts.

Source record: 64376

The only way to determine power radiated from an antenna at HF is to calculate it from its dimensions.

To simplify matters, one can neglect ground and other losses. In which case radiated power will be about 99.99 percent of power input from the transmitter.

About 90 to 95 percent is what you would get - PROVIDED a way can be found to measure it. Otherwise just take the calculated figures as being near enough.

The directions and elevations in which power is radiated are, of course, the answers to yet more important questions.

Reg.

Bob,
If you are comfortable with Lew's explanation, this shouldn't confuse
things, but one minor additional concept.
Regarding your comment:
"Is it correct for me to say that the actual losses really aren't all
that
significant or meaningful, aqnd (sic) that a good receiver, which I
have,
can easily make up for them ?"

While on HF atmospheric noise usually dominates, loss before the
receiver can not always be "made up" by a receiver. If we go up to an
otherwise dead frequency, say, up around 20 or 30 MHz where/when there is no
significant atmospheric noise, we have a slightly different situation.
S/N is still the thing to consider, but the noise of the receiver front
end may now be the dominant noise. Now, consider that the loss of the
feedline causes a reduction of the signal, but, of course, has no affect on
the receiver noise. This feed line loss lowers the signal and degrades the
S/N ratio. The only way to get better is to either reduce the feedline loss
or reduce the receiver noise (noise figure).

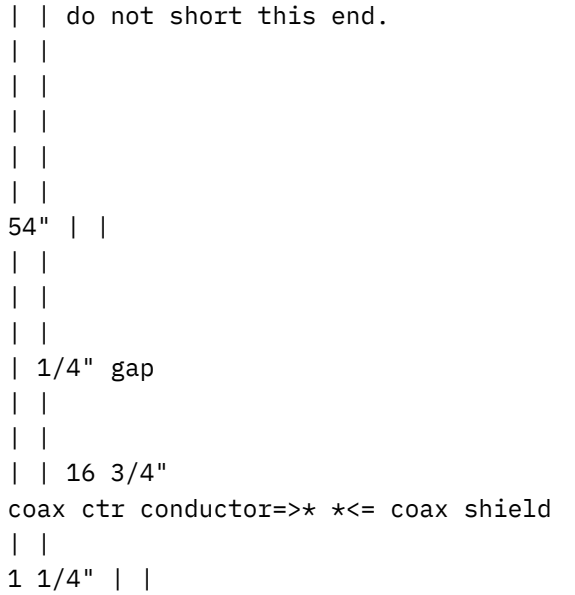
Kevin-

One version of the J-Pole antenna has the cable connected an inch or two
above the connection between the two vertical rods. The following article
from my archives, shows how it could be connected, except it is based on
Television Twin Lead instead of the two rods yours has. If you use a
mono-spaced font like Courier, it should be clear. The conductor above
the 1/4" gap is not essential, it just comes with the twinlead!

Fred

2M Jpole with 300 ohm twin lead
From: kinsman@ektools.UUCP (Andrew A. Kinsman)
Newsgroups: rec.ham-radio
Organization: Eastman Kodak, Dept. 47, Rochester NY

The following is a description of a J-Pole antenna made from 300 ohm
TV twin-lead. Quite a few of the hams in the area have successfully
built one or more of these antennas. They have quite a few advantages
which include improved performance for 2-meter HTs, portability, and
last, but never least, they are inexpensive.



-*-
solder the twin leads together at bottom

1. Start with 54 1/2" of TV twin lead (foam core does not work as well)
2. Strip 1/2" of insulation at bottom and solder wires together.
3. Measure 1 1/4" from soldered wires and strip insulation on both sides. This is the solder point for a coax feedline.
4. Measure 16 3/4" from bottom and cut out 1/4" notch on one side.
5. Feed with a length of RG58U coax. Tape coax at feedpoint to the twin lead for strength and weather protection.

I have also attached an alligator clip to the plastic on the top of the antenna in order to conveniently hang it. I am successfully using one in my attic to avoid any CCNR problems. I have another that I can take with me camping, sailing, etc.

This design has appeared on many BBSs and in club newsletters; the earliest reference that I know of is a Jan. 1984 D.A.R.C. antenna article by James Burks, KA5QYV.

Enjoy,
N6UBM

Only for DC or in-phase AC/RF.

Volt-Amps = Amps times Volts = SQRT(watts^2 + vars^2)
Watts = Amps times Volts times cos(A) = real power
Vars = Amps times Volts times sin(A) = reactive power

"Otherwise just take the calculated figures as being near enough."

Standard AM broadcast stations usually do that once their performance has been proved by field measurements.

A point in the system just before the power from the transmitter branches out to the towers in an antenna array is designated as the "common point" of the system. Here the impedance and current are measured to determine the power radiated by the system. Losses are considered insignificant, An r-f ammeter permanently installed here constantly monitors the station`s power.

Only if you're talking about instantaneous values, which people seldom do (but should). At any instant of time, the power at a point (that is, the rate of energy flow past the point) is the volts time the amps at that point at that instant. But if you look at, say, the energy moving between the inductor and capacitor in a high Q parallel resonant LC circuit, you'll find that nearly all the energy moving in one direction moves back on the alternate half cycle. That is, the instantaneous value of the power is positive for one half cycle and negative for the other. The average power is therefore relatively small, much smaller than the product of RMS volts times RMS amps. In the extreme theoretical case of a lossless circuit, the average power is zero, so there's no net long term energy flow even though both V and I can be very large.

Reg, I may be misuderstanding what you mean by "power input from the
transmitter", is it the same as the transmitter power output as
measured at the transmitter?

As you know, ground losses can be a major loss component in the case
of some types of antennas, for instance short Marconi type antennas.

If "other losses" as used above includes transmission line losses, it
is not infrequent that we see people describe configurations where
transmission line losses are in the range 10dB to 20dB (ie radiated
power less than 10% to 1% of the transmitter output respectively).

I shouldn't use that work ONLY!!!

Only in a DC circuit, or a in an AC circuit (loop) where the current
and voltage measured are in phase. In an AC circuit where the voltage
and current are not in phase you must multiply the product of the RMS
voltage and RMS current by the cosine of the phase difference to get
real power (which is what I think you mean by "average power").

Greetings,

You are invited to download and use the new version of WinCAP Wizard. The default download is known as QSL-ware. Which basically means freeware. <G>

This QSL-ware version provides unlimited point-to point and NCDXF beacon predictions, prefix search, numerous prediction views and more.

www.taborsoft.com

The registered version adds coverage analysis and user batch prediction modes. A 60-day trial key is available upon request.

If you use a competing tool, not to worry, they can surely add a few of the new features. <VBG>

Cheers,
KU5S

Of course, that only works when the voltage and current are sinusoidal and of the same frequency. More generally, the average power is 1/T times the integral over T of v(t) * i(t) dt, where T is the interval over which it's being averaged. If the waveforms are periodic, an interval of one cycle can be used for T.

Yes, implied by the "in phase" condition.

Thinking that through further brings a third case to the "ONLY"
conditions, and that is if the circuit is entirely resistive (eg real
power is the product of Vrms and Irms if the waveform is square and
the circuit contains only resistances).

there is no good way to measure the output power from an antenna. it is easy to measure the input power with a meter before the antenna... and 500w is not 'high power' to most of us, that is only 1/3 of what hams can legally run and we have to measure amplifier power all the time so there are lots of meters out there. Normally the best you can do is an estimate from computer modeling and then maybe back it up with a couple field strength measurements if you can set up a controlled enough test environment.

using infra red images of antennas might be interesting, but not very practical. it would basically only show you the temperature of the conductors and maybe help you find bad joints or really lossy high current spots, but it won't give you a power value.

If you look at the definition of average (as in my previous posting), you'll see that when the load is purely resistive, average power = 1/T * the integral over T of v^2(t) / R dt or 1/T * the integral over T of i^2(t) * R dt, for any waveform. And using the definition of RMS(*), you can see that this is exactly Vrms^2 / R or Irms^2 * R respectively, again for any waveform. So Pavg = Vrms * Irms for any waveform, as long as (and only as long as) the load is purely resistive. Again, the average and RMS values can be calculated for any interval (as long as they're the same), but a single cycle is adequate to determine the long-term average and RMS values of periodic waveforms.

(*) frms = Sqrt(avg(f^2(t))) = Sqrt(1/T * integral over T of f^2(t) dt)

1434. Stealth antenna question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-14 23:46:54 UTC
From: "Joe S." <anon@mous.com>
Message-ID: <5eudnRTUMuRG9m_eRVn-qA@comcast.com>
Source record: 64395

I am considering installing a stealth antenna on the porch of my first-floor apartment and would like some suggestions. Here's the deal.

-- First floor apartment.
-- Porch is a concrete slab, 10 X 10.
-- The ceiling of the porch is the underside of the balcony of the apartment above me. It's all wooden.
-- Thus, the ceiling of my porch is 10 X 10, wood.

How about I build a 40-meter dipole, 67 feet long, feed with coax and a balun in the center. Attach the coax and the balun to one of the corner posts that supports the balcony above my porch. Run the two sides of the dipole in opposite directions, but, instead of stretching the wire straight as I normally would if hanging the dipole from trees, towers, etc., what if I run the wires around the underside of the balcony deck? This would give me a horizontal loop made up of two pieces of wire, each 33.5 feet long, with the loop being 10 feet on a side, thus, each end of the dipole would run around underneath the balcony deck and come back almost to the center of the dipole.

That is -- the balun would be secured to one of the corner posts. One piece of wire, 33.5 feet long would run straight out from the balun along the 2 X 8 rim joist for 10 feet, make a 90-deg turn (20 ft), run another 10 feet and make another 90-deg turn (30 ft), and end up 3.5 feet after the third turn. The other end of the dipole would do the same thing, only run in the opposite direction. At the balun, the two wires making up the dipole would run at a 90-deg angle to each other. And, the two wires would overlap (or be only a few inches apart) for 27 feet of their length.

I probably didn't explain this idea too well but I'd like to hear some suggestions. Thanks.

This is probably a good place to mention that people interested in the relationship between RMS voltage and current and average power (and the uselessness of the RMS value of power) can find an explanation at http://eznec.com/Amateur/RMS_Power.pdf. It doesn't use any mathematics more advanced than a square and square root, so any amateur should be able to understand it.

Some time ago I was surprised to find this to be one of the most frequently visited pages at my web site, apparently due to a link in the Wikipedia entry for RMS.

To measure the output from an antenna, measure the input as others
have posted. What you should really be interested in is the increase
in signal power at your target receiver when increasing from power1 to
power2.
To really observe antenna radiated power involves incasing the
antenna in a sphere, and calculating the power density at the edges of
the sphere. I am not an antenna engineer, so could be wrong, but this
involves triple integerals.
About the best a ham can do is an FSM and a modelling program plus an
idea of where you would like to talk to.

The other answers aren't wrong, but measuring power within the antenna/transmission line system can be misleading because not all the power measured there is actually radiated. Some is dissipated as heat in the matching unit (if used) or reflected back to the transmitter. Radiated power doesn't go in all directions, either.

The output power from an antenna is often described as such-and-such "field strength" at some standard distance and it is determined only with expensive test equipment. Because of directional effects, making just one measurement often isn't enough.

You set up equipment at a fixed distance from the antenna (perhaps a mile) with a special receiver, one with a meter calibrated for input signal strength at the antenna terminals. A spectrum analyzer may also be used, but you have to be very careful about overloading its wide-open front end, not with your transmitter, necessarily, but with every other darn thing in town.

You feed it with a particular test antenna, one which will be supplied with a set of calibration charts. Read the microvolts from the receiver, correct for cable losses and use the calibration charts for the antenna to yield the signal strength in standard units, like microvolts/meter. I do not remember

the antenna names, but I do remember one receiver was the Singer NM-25.
That mama weighed about sixty pounds.

If you go to a vendor site, like www.tucker.com, you can appreciate the
variety of equipment available for quantitative measurements.

I worked as a certified EMI Engineer from 1988 until 2002 and I hope I have
provided some useful information.

When we did 75m mobile shootouts, we measured the forward power
and reflected power and assumed the net power was reaching the
antenna. We measured the field intensity about 1/2 mile away
using a ferrite rod pickup coil. Of course, all antennas were
loaded vertically polarized monopoles with approximately
omnidirectional characteristics.

Thanks for the warning but this is not much of a consideration. The
apartment is rented full-time by a local corporation and it's used

occasionally, a few days at a time, by traveling executives who generally come to town, check in late at night, leave early in the morning, and put in long days while they are here and never go out onto the balcony.

The real problem is going to be that winding the antenna back on itself
like that has the effect of lowering its radiation resistance. I ran it
up in Mininec and it comes out to less than 1 ohm at resonance. At that
rate, you'd be better off making a dipole of two screwdriver antennas
back to back.

1442. 300 ohm folded dipole from ARRL Handbook, early 1990's

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-15 08:11:03 UTC
From: gsm@mendelson.com
Message-ID: <slrndv5o0l.jp4.gsm@cable.mendelson.com>
Source record: 64403

Hi, the early '90s ARRL handbooks had construction information for a simple folded dipole made of 300 oHm twinlead. The article was not in the '96 edition or later.

The antenna was made of 300 ohm twinlead. It was fed in the center by a 300 ohm twinlead feeder to a matching capacitor which made it aproximate 50 ohms. The capacitor could be either a regular capacitor (I used silver mica WWII surplus) or a "stub" of more twinlead.

At the end of the feed line, which was part of the antenna, you could attach it directly to a 50 omh unbalanced transciever or a 50 ohm coax of any length.

The length of the antenna was one half wavelength without the velocity factor and then shorted at the wavelength points compensating for the velocity factor.

For example, if it was 10 meters long for a 20 meter dipole, the shorts were about 4 meters from the center for twinlead with a velocity factor of 0.8.

If anyone has a copy of the article and could scan it for me, I'd appreicate it, or even better yet, a pointer to an online version of it.

Thanks in advance and 73,

BTW, if you are also in Israel and asking yourself "where does he get the twinlead"? I don't. I brought it with me when I moved here in '96.

Geoff.

1443. Orthogonality relation between modes in Dielectric-Lined Circular Waveguide (or with concentric dielectric layers)

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-15 08:23:57 UTC
From: skatsis@ee.duth.gr
Message-ID: <1139991837.392371.176510@g14g2000cwa.googlegroups.com>
Source record: 64404

I am working on dielectric-lined circular waveguides and I am searching
for a reference on the orthogonality of modes. The only thing that I
found is in the link below (at the bottom of the message)
but I am looking for something with more details.

Assume that we have a uniform cylindrical waveguide with N concentric
dielectric layers [my case of interest is when N=2, and we have the
waveguide with a thin inner dielectric layer (second layer N=2) and the
rest is vacum (air-> N=1-> first "layer")].
I need an orthogonality relation that applies between any two modes.
The fact is that I already have found an orthogonality relation (see
the link below) but I need a more detailed analysis.

http://www.bnl.gov/ATF/experiments/Dielectric/2-Theory_of_Wakes.pdf

IF ANYONE KNOWS SOMETHING PLEASE ANSWER THIS MESSAGE.

Sounds like a scaled up version of an antennas I built from a design
called 'The Mighty Wide 6M Dipole'... The design came from the internet
I think, I seem to recall G0IER published it on his website. I have also
seen the scaling information for other bands...

Hope that's of some help...

> seen the scaling information for other bands...

Thanks, but it led to some questions.

Here is the web page I found for it: http://www.qsl.net/g3pto/6m_dipole.html

From my calculations, assuming his center frequency was 51 mHz, he used a size factor of 142.494 for the total length of the antenna. This seems odd to me, as it would translate to 467.5 feet which is number I've never seen before. Either something is amiss in my calculations, or he used a different center frequency or just an unusual number.

The shorted length makes perfect sense, the ratio of total to shorted is .8425 which is a reasonable velocity factor for 300 ohm twinlead.

The length of the stub makes no sense to me at all, but I'm sure he had his reasons.

Using the proportions he used, I wrote a perl program to calculate the size for any frequency.

For six meters, it matches his dimensions with a center frequency of 50.1 mHz:

for frequency 50.100 mHz.
total length 9 feet 3 inches or 2.844 meters.
shorted length length 8 feet 10 inches or 2.396 meters.
difference length length 0 feet 8 inches or 0.224 meters.
stub length length 0 feet 11 inches or 0.298 meters.

For 20 meters (14.175 mHz center frequency) I got:
for frequency 14.175 mHz.
total length 32 feet 11 inches or 10.052 meters.
shorted length length 32 feet 9 inches or 8.469 meters.
difference length length 0 feet 7 inches or 0.792 meters.
stub length length 0 feet 5 inches or 1.052 meters.

Anyone have any ideas? Will this work? How do I calculate the stub length?

The ARRL Handbook antenna (not to be confused with the ARRL Antenna Handbook, which he used) was slightly different, although this would work too if my calculations are correct.

Geoff.

I don't know your budget, but the SGC Stealth Kit sounds like what you need. It uses an automatic tuner and an 80 foot length of wire that can be configured as a multi-loop. In your case you would string the wire twice around the wooden ceiling. I am in the process of installing one in my third floor attic. I will have to use a four turn loop to fit the space.

Good luck, jimbo

Thanks for noticing that.

I had the feet part of them being zero, when they should have been
greater. It was stupid testing, it worked right at 51 mHz, where they
were zero. I didn't look at the 14.1 mHz numbers closely enough.

Here is the correct numbers:

for frequency 14.100 mHz.
total length 33 feet 1 inches or 10.106 meters.
shorted length length 32 feet 11 inches or 8.514 meters.
difference length length 2 feet 7 inches or 0.796 meters.
stub length length 3 feet 5 inches or 1.057 meters.

Just another proof that programmers should NOT do quality assurance on their
own work.

73,

Geoff.

Did you actually read the paper you referenced?

Two points:

The authors note on the third page that they could not find any prior derivation of the orthonormality relationships for this configuration. The paper was published in 2000, so it should be an easy library research project to find any subsequent papers that reference this work.

Appendix A goes through the derivation of the orthonormality relationships in excruciating detail. Every step is outlined, including the integration tricks. It is unlikely that you would find any paper, or even a textbook, that is more detailed.

> a 300 ohm twinlead feeder to a matching capacitor which made it aproximate
> 50 ohms. The capacitor could be either a regular capacitor (I used silver
> mica WWII surplus) or a "stub" of more twinlead.

Assuming the SWR on the 300 ohm twinlead is 1:1,
you want to install a capacitor that causes an SWR of 6:1
on the twinlead between the capacitor and the 1:1 choke/balun.
300+j0 in parallel with 0-jXc needs to result in 60-j120 ohms.

The reactance of the capacitor should be -j150 ohms and it should
be positioned 0.062 wavelength from the 1:1 choke/balun. For instance,
for 7.2 MHz, the capacitor should be 147pf and be positioned
7.7 ft. from the 1:1 choke/balun assuming a VF of 0.9.

468/f is the length of a dipole adjusted for end effects.

Why not use a Xc = -j150 cap? I get 0.176 wavelength for a
capacitive stub which may be inconvenient at HF.

Actually, shorting the antenna at an intermediate point between the center and ends rather than just at the ends doesn't make much sense.

The feedpoint impedance of a folded dipole consists of four times (or other ratio if the conductors are different in size or there are more than two folded conductors) the impedance of a standard dipole, in parallel with two series connected shorted stubs. The dipole consists of the two conductors in parallel. This behaves as a single fat wire which has the effective velocity factor of ordinary insulated wire, around 0.97 or 0.98 that of bare wire. That's why a folded dipole is about the same overall length as a standard dipole. The stubs have the physical length of half the dipole, or a bit shy of a quarter free space wavelength. Unlike the dipole part, they operate as transmission lines, so their velocity factor is around 0.8 -- a value which varies somewhat with cable construction. Folded dipoles are sometimes shorted about 0.8 of the way from the center to the ends in an apparent attempt to make the stubs an electrical quarter wavelength, resulting in their impedance being very high as seen at the feedpoint.

But if the intermediate short circuit isn't done, the effect of the somewhat longer stubs is only to add a bit of capacitive reactance across the feedpoint. This lowers the antenna resonant frequency roughly 50 kHz at 14 MHz, and has very little effect on the feedpoint resistance. Antenna resonance can be restored by simply shortening the antenna a little. So why bother with the intermediate short?

The 1986 handbook has the details for this type of antenna on page 33-14, under the title of "Simple Antennas for HF Portable Operation." For 7.15 MHz, the value of the capacitor is 152 pF, and the length of the matching stub is 6'11-1/2". An open-end stub, made from twin lead, of length 20'-1/2" can be substituted for the capacitor.

Thanks -- I'll check it out.

I have an extra ATAS-120 -- it's a long story -- my original ATAS-120 went under (salt) water in Katrina along with my truck. I removed the antenna from the truck and the insurance company took the rest. I replaced my drowned FT-857 and ATAS-120 and truck and installed the new rig and antenna on the new truck.

Last week, I took the drowned ATAS-120 apart, cleaned it up -- there was very little corrosion, probably because of the seals on the antenna -- tried it on my truck in place of the new ATAS-120, and it's working fine.

I may try to mount the old ATAS-120 on my porch railing (wooden) and figure out a way to ground it and use it as my apartment antenna.

XYL and I are refugees from Katrina -- we were living in an apartment in Bay Saint Louis, MS, and building a house nearby -- it was all washed away in Katrina and we took a big uninsured loss. We are now looking for a home here in NE Tennessee -- 1,500 feet or more above sea level.

I may just wait until we find a house because we are looking for houses with land attached and I feel an antenna farm coming on!!

It might be interesting to some to explain how/why this works.
On a feedline with reflections, there are purely resistive
current maximum points existing every half-wavelength up and
down the feedline. Since the resistance at the current maximum
point is often in the ballpark of 50 ohms, this is often
a logical point at which to connect the transmitter/tuner. That's
why I feed my 130 foot dipole at a current maximum point on each
HF band.

However, for a folded dipole with a 300 ohm resonant impedance
fed with 300 ohm feedline, there are no reflections and therefore
no current maximum points because there are no standing waves.
So the trick is to cause a 50 ohm current maximum point to occur
by causing reflections and standing waves on a short piece of
series matching section. A parallel capacitor can often accomplish
this function. Obviously, a capacitive stub can do the same thing.

Note: the following calculations were done with a paper Smith Chart
and therefore suffer from some inaccuracies.

A parallel capacitive reactance of -j150 ohms will shift the 300+j0
ohm impedance to 60-j120 ohms. Some may want to refresh their
memories on the parallel/series and series/parallel impedance
equations.

60-j120 ohms will cause an SWR of ~6:1 from the point where the
capacitor is installed on a flat 300 ohm feedline to the necessary
1:1 choke/balun. If we divide the 300 ohm Z0 by the SWR, we will
obtain the resistance at the 6:1 SWR current maximum point. That
value is 300/6 = 50 ohms and it exists ~0.062 wavelengths
farther along than the 60-j120 point where the cap is located.

The cap needs to cause an SWR of 9:1 if flat 450 ohm line is used
and 12:1 if flat 600 ohm line in used. Needless to say, the Z0 of
the line determines the value of capacitive reactance that is
necessary to accomplish that function.

Some thoughts on why it might not work to plan, though it should be close to plan and capable of fine adjustment if needed.

Worth noting that the characteristic impedance of some lines is quite different to their market labelling, especially 300 ohm and 450 ohm lines.

In this part of the world, nominal 300 ohm TV ribbon is more like 360. Wes measured a range of nominal 450 ohm lines to be from 360 to 400 ohms.

Although the calculated answer might be a shunt capacitor of 147pF, in practice a close value would be used and both the dipole length and feedline length could be juggled for better match if needed. Alternatively, a shunt stub could be used and tuned along with the series line length.

The feed point impedance of the dipole will depend on its environment to some extent, and may be reactive if formulas are used to cut it to length.

Of course, it is a one-band matching arrangment.

Roy Lewallen, W7EL wrote:
"The average power is therefore relatively small, much smaller than the product of RMS volts times RMS amps."

RMS is short for root-mean-square. RMS is synonymous with the "effective value" of a sinusoidal waveform.

Therefore, the average power for the time period of one complete cycle or any number of complete cycles is the product of the effective volts times the effective amperes.

See page 19 of "Alternating Current Fundamentals" for derivations of the proof.

Average power is exactly the product of rms volts times rms amps in usual circumstances.

Leaving aside your new confusing term "effective value", if you multiply Vrms by Irms in an AC circuit you get Apparent Power (units are Volt Amps or VA).

Apparent Power is the vector sum of two quadrature components Real Power (Watts) and Reactive Power (VAR).

Real Power is the thing you describe when you talk about average power. It is Real Power that is the rate of flow of energy averaged over a complete AC cycle.

Depends on what you mean by "usual circumstances". Your rule does not apply if there is a phase difference between V and I, which is commonly the case in power distribution, and is commonly the case in RF where loads circuit impedances may have a reactive component.

To an electrician, (Real) Power = Vrms * Irms * PF where PF (the power factor) is the cosine of the phase angle between V and I. This isn't engineering stuff, sparkies know and apply it every day.

Close is all most of us need. Once the 50 ohm SWR is below
about 10:1, the fine adjustments are relatively easy. If the SWR
decreases with adjustments, we are going the right direction.

No, I'm sorry, that isn't true. The average power isn't the product of the product of the RMS voltage times the RMS current, except in the single circumstance of their being in phase.

> See page 19 of "Alternating Current Fundamentals" for derivations of the
> proof.

I don't have this book, but I know that in the past you've quoted from books without having fully understood the context of the quote. I'm sure that's the case here. Any electrician or technician should know that for sinusoidal waveforms, Pavg = Vrms * Irms * cos(theta) where theta is the phase angle between V and I. And hopefully you can see with a few moments and a calculator that if theta = 90 degrees, Pavg = zero regardless of V and I.

> Average power is exactly the product of rms volts times rms amps in
> usual circumstances.

Perhaps your "usual circumstances" are that the load is purely resistive. But that's not "usual circumstances" for a host of applications.

How about P = Square(V) / R watts

or P = Square(I) * R watts

for no phase angles.

Those are fine by me.

Just for the record, though:

V is the voltage across R, I is the current through R. This is important when there are other components, hence possibly other values of V and I, in the circuit. P can be average and V and I RMS; or P, V, and I can all be functions of time -- the formulas are ok in either case. And finally, just for the fuss-budgets, we're assuming R isn't varying with time.

Picky as this might seem, it's awfully important to make perfectly clear just what a formula applies to and what it doesn't. Otherwise it's sure to be misapplied in situations where it isn't valid. (Clarification reduces the chance of misapplication from certain to only highly likely.)

Yes. The voltage drop across a resistor is always in-phase with the current through the resistor as there is no energy storage in a resistor.

Ken,
More radials are better. If possible, add the 4 33' radials to existing
10' radials.
Radials lower the loss to verticals, and increase overall performance.

I've noticed something else on this problem, below the 3-phase electrical conductors, there is either a telephone or catv wire. The intense periods occur when I drive by some type of device that loops this cable in to a pear shaped configuration. I guess it's not a periodic sound but appears that way because they are evenly spaced and I drive the same speed.
Maybe if anyone is still following this thread and that sheds anymore light they'll respond.

Exactly, except the term "effective value is as old as a-c power calculations. The value of the a-c volt was chosen to produce the same effect, lamps as bright, heat as warm, as d-c does.

My electronic dictionary says:
"rms amplitude - Root-mean-square amplitude, also called effective amplitude. The value assigned to an alternating current or voltage that results in the same power dissipation in a given resistance as dc current or voltage of the same numerical value.'

To anyone who may be interested.

In the notes to this new program I omitted to say that the computed components of plate current constitute the first few significant terms of a Fourier Series.

There's the DC component, the fundamental frequency component, and the 2nd, 3rd, 4th and 5th harmonic components.

The amplitude of the harmonics decrease as the harmonic order increases. Amplitudes are the peak sinewave values (not rms).

If the components, including the DC component, are added together taking into account their signs, then their sum is very nearly equal to the computed peak instantaneous plate current. Which has been adjusted to equal the actual value which flows in the tube.

If the Fourier Series had been extended to even higher harmonics then the sum of the series would have converged to the peak instantaneous value of plate current exactly.

This is a check on the accuracy of the Fourier Analysis performed by the program. There's ample oportunity for bugs.

If an amplifier is used as a frequency multiplier then power can be extracted from the plate by an LC circuit tuned to the required harmonic.

The correct plate load impedance is the required peak RF volts across it divided by the peak amplitude of the plate current component. There is NOT a conjugate match. The internal resistance of PA's is NOT 50 ohms as is commonly believed. With pentodes, beam tetrodes and transistors (transistors have operating angles) it is often much higher.

There, I've said it again!

Reg, G4FGQ.

Program OP_ANGLE

The Fourier Analysis of plate current has now been extended from the
5th up to the 7th harmonic. Otherwise the program has not been changed
except for the issue date. If you are still interested, download the
new version and use it to overwrite the first.

It seems that for almost exact agreement between peak plate current
and the sum of the harmonic components it is necessary to extend the
analysis up to around the 20th harmonic. There's not enough room on
the screen to display results.

I played a lot with a folded dipole for 14 MHz, both with twin lead and with
two parallel wires about 20 cm apart.

To feed it, I used a simple 75 ohms to 300 ohms Neosid transformer
currently/formerly intended to connect a 75 ohms VHF television set to an

antenna with twin lead. Depending on the country, such a bal/un is called a "symetriser", a "bazooka", a "pig's nose", etc...

This small pig's nose can cope with 100 watts output on 14 MHz and higher.

I never tried it on lower frequencies. I expect it would get rather warm on 80 m.

Richard, your discussion here is limited to DC circuits.

Your proposition in another post that Vrms * Irms gives the Real Power (ie indicates net energy flow over time) does apply to DC circuits, but it does not apply generally.

You have cited a text book to support your position, however it is likely that you have misinterpreted the text book.

Work this example through with your textbook:

We have 120Vrms AC 60Hz (sinusoidal) impressed across a load of 85 ohms of resistance and an ideal inductor of 85 ohms reactance in series. The load impedance is 85+j85. The Circuit current is 120/(|85+j85|) or 1Arms.

The power dissipated in the resistance is 85W, and since it is the only resistance dissipating power, the Real Power for the entire circuit is 85W. The circuit Apparent Power is 120 * 1 or 120VA, the Reactive Power is 85VAR.

The circuit Vrms * Irms does not give the Real Power for this circuit.

Owen

I am tryng to use a Sansa M240 MP3 player and FM radio on my motorcycle, with the output going into a helmet sound system (Starcom1). This means that the headphones -- which usually act as the FM antenna -- will not be used.

I would like to try using a splitter on the headphone jack, with one leg to the helmet sound system and the other leg to an antenna. My first thought was a simple 1/4-wave dipole to run around the fairing perimeter. Would that work? Would I need to add some passive components or some matching because the device expects the headphones to be the antenna?

And, Yes, the Starcom1 also interfaces to a TH-F6A tri-bander.

Yes it is. Sorry I fat fingered (E=1ampere). It is I=1 ampere.

1 ampere times the 85 volts dropped across an 85-ohm resistor by 1 ampere = 85 watts, same as 1x1x85=85, or 85x85/85=85. All methods of calculation must give the same answer, and they do if you don`t make a mistake.

The shield on the headphone cable is used as the antenna for such devices. As for matching, how good of a match can a headphone cable be? Inside most radios the connection is a single cap, in the pF range, between the jack and the RF front end. Oh, and some kind of choke for DC continuity for the audio part. Strip away some of the plastic jacketing around cable at the FM radio end, and solder on an extra wire to the shield. Route the wire some place convenient. You'll have to experiment for best reception. Just keep it away from any noise and power sources, like spark plugs, transmitters, Illudium P-36 Explosive Space Modulators.

Life's a highway -- get on and ride,

In the spirit of Field Day, the RARS Group was created to promote remote field and mobile operations. RARS Group is open to all licensed amateurs who enjoy operating from the field, mobile, marine or remote base locations. You can even set up your station in your backyard and join the fun. Modes of operation are SSB, CW, QRO or QRP.

So if you enjoy the outdoors and working from the field or from your boat, car or truck somewhere in the middle of nowhere, we invite you to join us and make everyday a field day.

You can visit RARS at: http://rarsgroup.com

Thanks & 73

1486. using coax shield to create a loading coil ?

Newsgroup: rec.radio.amateur.antenna

Good morning. I would like to experiment with making a high Q coil for creating a tuned radial counterpoise. Reg's program predicts a coil of about 70 uH will create a match. One way to create such a coil would be to wind coax and use the shield as the conductor. Besides the obvious loss of physical stability due to lack of a form what are the limitations or drawbacks from using the shield?

Thanks - Dan - kb0qil

The braided shield will be substantially lossier than a solid wire or tube of the same diameter. And the relatively poor quality dielectric used for the outside of the cable will also reduce the Q somewhat. So coax isn't a good choice for your stated objective of making a high Q coil.

The sheath is easy to strip.

Two factors. One is surface roughness. The other is caused by the current having to continually move from one group of wires to another as it travels. I'm just now doing some research on how significant these effects are, but so far I've found out they're very noticeable. It's one of the reasons the loss of typical coax is substantially greater than predicted with idealized programs or calculations that fail to take these factors into effect.

True enough, but my guess is that the resulting water and crud you'll be getting among the fine wires will be worse than the insulation.

But hey, you don't have to believe me. Make up some coils and measure their Q -- it's not hard at all. Then stick them outside for a while and measure them again. Or do like most amateurs do -- make the coils, discover that you can talk to far away places "barefoot", and declare that they "work".

You may have better luck by using sone soft copper tubing. Dimensional stability would be one advantage.
You could use ScotchKote or some insulating paint if you needed it to be insulated.

Skin effect is well known. On a good conductor at high frequencies, current is concentrated very near the surface. When a bundle of wires ducks under another in the direction of current flow, the current has to migrate to the outside again, which means it has to move from one conductor to another. There's no question that it happens -- what's a bit harder to pin down is just how much loss typically results.

>> I'm just now doing some research on how significant these
>> effects are, but so far I've found out they're very noticeable.

Books, and to a lesser extent the web. Information about this is scattered among a number of sources. Quite a few discuss surface roughness in a general way, but there's a particularly good explanation, analysis, and something of a quantitative treatment in Johnson & Graham's _High-Speed Signal Propagation: Advanced Black Magic_. The effect of weaving is harder to track down -- most authors simply assume coax shield conductivity loss to be negligible, and don't deal with woven conductors in any other context. But it really isn't, if you're interested in good accuracy. And of course when the braided conductor is the primary conductor, it becomes much more important. I know Tom, W8JI has done some measurements on braided vs solid strap, and I'll be asking him for more information before long. I do know that he found a very significant difference, and I have a great deal of respect for his experience, measurements, and opinions.

>
> What would be a good way to measure Q?

The way I do it is by resonating the inductor with a parallel air variable capacitor. It's important to keep it away from just about everything. I couple in and out with a very small (typically 1 pF at HF) capacitor, and make sure that the impedances of the source and detector are either very high or quite low (say 50 ohms) to minimize loss. I use a signal generator for the source and a scope for the detector. Using a

frequency counter connected to the signal generator, I measure the resonant frequency and -3dB points. The Q is the ratio of the center frequency to the 3dB bandwidth. For convenience, I made a 3dB pad I can switch in an out of the signal generator. With this, you don't even need a linear detector, and a diode and meter would do. My measurements have been within about 5 - 10% of readings with a good HP Q meter on the few occasions when I've compared them. That's close enough for my purposes.

Roy,

Thank you. It is a quick experiment to build a test coax coil and measure the Q. That should produce enough evidence to test a counterpoise.

In the mean time the research to build a coil out of copper tubing continues. So far the only alternative I can conceive is to make a wooden form and wrap the coil on the outside.

Thanks again - Dan

You have cited the major limitation: physical form. matching coils for many broadband transmit antennas use wound coils of roughly that dimension, although they are made of copper tubing that exhibits much more stability, once shaped. May I suggest the use of PVC pipe as a form for winding the coax? Tape it in place while you're "monkeying" and then fiberglass it when you like what you have. (Auto supply stores sell the fiberglass for doing auto body work -- it's durable & light-weight.)

OK - I just bought a new in the box 1955 Heath GD-1B grid dipper with the extra low band coil set. $25. The dipper works FB and I used an old SO-239 chassis jack plus a bit of 22g wire and a cut down pill bottle to make a 4t coupling loop big enough to "dip" - that is I inserted the dipper's coil inside the pill bottle coil attached
to my feedline.

Now here is where I make myself look stupid - My antenna's best SWR is at 7185 with a 1.1:1 but the dipper showed max dip at 6990 (I tuned into the dipper with my K2). What's going on here?

Someone educate me.....lol

Roy,

As we dumb amateur radio down to make it attractive to the
disinterested masses in a desperate and mistaken persuit of increasing
the number of licenced hams, this is becoming the new standard of
understanding in the redefined amateur radio.

I wrote comment on an a recent article in Australia's ham radio
magazine "Amateur Radio" that was an example of the declaration of not
just something that works, but "something that really works" though it
looks to be quite inefficient on at least one band. The comment is at

http://www.vk1od.net/blog/index.php?op=ViewArticle&articleId=21&blogId=1
.

Supporters argue "amateur radio is about having QSOs, so if you have
QSOs then the antenna works... QED".

Though antenna systems remains one of the few areas of amateur radio
where hams can cost effectively design solutions specific to their
location and needs, the lower competency standard of the new
"communicator" style amateur does not support a soundly based
understanding of antenna systems. We frequently hear the argument that
there is no need to understand electronics for modern amateur radio
where commercial radios are the norm, but forget electronics for a
moment, how many hams understand a common three component passive
network that is so often employed with variable results, the ATU.

Get used to it! Amateur radio is being transformed to "I just wanna
talk on the radio".

Again, interesting, but what's been outlined so far is not scientific.
For something of this nature to be of any utility, it must be grounded
in science.

Hmm. Well, the shield on the shielded stereo cable between the player
and the helmet sound module might pick up some interference from the
motorcycle's electrics. What components would you suggest that I
install on that cable to filter that out? Basically, I would want to
filter out everything that is not audio frequency (20 Hz - 20 kHz) or
between 88-108 MHz.

The player headphones have a main cable that is 29" long before
splitting to each headphobne. This is 1/4 wave for FM BCB. I could,
as you suggest, splice in a 29" wire at the player end of the cable.

The skin effect is most thoroughly grounded in science. What you seem to be unaware of is that it's *so* well-known that, in any discussion about RF engineering, the scientific proof of its existence can be 'taken as read'.

For a detailed scientific proof of the skin effect, try:
http://tinyurl.com/brpq6

That proof is more general - and hence more powerful - than the ones you find in most engineering texts such as Terman. It demonstrates that, if an RF current is flowing across *any* conducting surface (not restricted to any particular shape or cross-section) and also for *any reason* (not limited to any particular kind of circuit or device) then there will be a skin effect.

That's the science of it; now back to the engineering.

What Roy said was quite correct. Braid is a kind of composite conducting surface, made up of the exposed surfaces of the individual strands. The skin effect means that the outside of the composite surface must always carry the highest RF current density (amperes per square micron of cross-sectional area). So whenever the weave of the braid makes an exposed strand dive below the surface, the RF current must cross over to the next touching strand that is still exposed. A little way further along the braid, it will have to cross over again... and again, and again.

It is hard to visualize exactly how these crossovers happen on a microscopic scale, but the physics of the skin effect dictate that it *must* happen somehow. Obviously physical and electrical contact between the two strands is required. We also know that electrical contact works better when there is a strong force pushing the two conductors together, because the force deforms the two surfaces into each other, to give a greater contact area.

The key fact is that the contact forces between strands in a braid are very small and unreliable. That means the RF resistance of a length of braid will be significantly higher than for a smooth conductor with the same external surface area.

Then it gets worse. Even the thinnest film of corrosion can disrupt the contact between copper strands in a braid. Unless the current density is large enough to break down this film, it means the RF current is forced to flow into the interior of the braid. Again the exact geometry is hard to visualize, but again the physics dictate that if an isolated 'filament' of current is forced to flow beneath a conducting surface, the voltage drop per unit length must increase - in other words, the RF resistance must increase.

Scientific deduction has told us that all these effects must exist. Whatit cannot tell us is how big they are in real braid, or how important they are in practice. For that we'll need some measured numbers.

You have two choices here: either look for existing measurements from people who have demonstrated their competence and scientific approach; or do it yourself.

Mike, leakage and inductive and gap effects in woven braid has been in
the science literature for over 40 years. To keep this discussion
focused I have emailed one specific reference to Roy. Hopefully Roy has
the time and resources to do the research and make the results available
to us in terms we can understand.

Resonance and VSWR are NOT related!

My 75 meter mobile antenna is resonant at 3.94 MHz. My VSWR is 5:1.

You are measuring two different things.

The dipper is a very nice tool. I owned the Heathkit unit in the olden days. I now use the Military surplus AN/PRM 10.

> Thanks again - Dan

A copper tube will definitely produce an improved Q. If you do make comparative measurements of ones made from tubing and from coax, please post the results.

A real problem in maintaining the Q of coils outside in the weather is keeping water from getting between the turns. Water is very lossy stuff at HF, and it has a very high dielectric constant. The two combine to make it a real Q killer if it gets into any region of high electric field strength. A bit of accumulated dust mixed with the water makes it worse yet. So if you anticipate leaving the coil on a form and exposed to the weather, also check the Q when the coil is wet. See http://www.eznec.com/Amateur/Articles/Portable_Feed_Lines.pdf for results of measurements of wet and dry 300 ohm twin lead. It's not quite the same situation, but the loss mechanism is essentially the same.

I recommend that you do some modeling or just simple calculating, if you haven't done so already, to see just how high the Q has to be in order to keep overall loss acceptable.

One final thing to keep in mind -- I've heard reports of poor performance of elevated verticals being tracked down to badly imbalanced currents in the radials. Apparently even small physical differences among the radials can cause one or two to hog all the current. If this is so, it seems to me that making them more sharply tuned by inductive loading might make this effect even worse. So when you get the thing up, I suggest measuring the current in each radial. This is easily done with a toroid core with a few turns for the secondary and a fairly low R across the secondary. It's been discussed a number of times on this newsgroup, the last time quite recently.

Good luck!

1. Although it's usually close for simple antennas, the point of minimum SWR isn't necessarily the resonant frequency. The dipper measures resonance.

2. The coupling loop adds inductance to the circuit, lowering its resonant frequency.

I can assure the readers that all the effects I've discussed are soundly based on very well known principles. Anyone truly interested in the topic can find ample confirmation of what I've said, although it might take a bit of digging. The Johnson and Graham text is an excellent place to start.

What's lacking is good measured data for typical shields, and even that's going to have limitations because of the wide variations among cables and manufacturers. But even some rules of thumb will be useful.

But you've shown an interest in the topic. Why don't you make some measurements of coils made from tubing and from coax shields and report back?

Just my 29 cents worth... I don't think using real thick
copper tube, coax shield, etc, will really be worth the trouble,
vs using a standard wire wound coil on a form. There is some
increase in performance , but overall it will be fairly small unless
the
wire used in the standard coil is very thin. Once you get to about 1mm
thickness, you will have fairly decent performance. 2mm is even better,

and any increase using a thick tubing will basically be a waste of
time.
I think anyway... The spacing of the wires, and keeping water, etc
from between the coil windings is more important. You can wind a
coil using 14 gauge wire and have a very high Q coil, if wound right.
Even 18 or 16 gauge won't be too bad as long as there is the proper
spacing between windings. Again, just my opinion from building various
mobile antenna coils... I'm pretty picky about my mobile antennas, but
I don't bother using "fat" coil conductors. To me, not worth the extra
trouble, weight, etc. I don't think the extra performance is that great
vs any regular wound coil , that has the proper pitch. With the thinner
wire coils, it's using a close winding pitch, with the wires nearly
touching that makes for excess loss. Not really the thin wire in
itself
unless it's super thin like magnet wire. And yes, I avoid braid for
anything
carrying rf. Even my grounding straps are solid.

The devil is in the details. Modeling shows large coils with 1 mm wire have a Q in the range of a few hundred. On the other hand a coil with 12 mm tubing has a Q of about 2000. The R of the 1 mm coil is about 6 Ohms while the 12 mm coil is on the order of 1 Ohm.

Given these model results it says there is a significant difference between 1 mm and 12 mm coils.

I've been away from that measurement field [integrity of coaxial braid shields] for almost 15 years. Measured data does exist for the effects of shield parameters [weave angle, optical coverage, # strands {picks}, wire gauge, etc.] based on using traveling wave excitation of the braid itself in either quadraxial test fixtures or over a controlled ground plane with known Zo between the cable and the plane. Test methods are IEEE defined [after 15+ years I can't recall a specific IEEE Test Method reference]. These quantify a 'leakage inductance'.

Hi Dan,

In the details, indeed.

What is the LENGTH of wire in this 6 Ohm resistor? What is the LENGTH
of wire in this 1 Ohm resistor? How many turns are in these "large
coils?" What is their diameter? What is their solenoid length?

Without these details, there is nothing said that is significant.

1512. Accuracy of Q meters

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-18 18:31:22 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dt7p5p$2ud$1@nwrdmz02.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 64373

There are inumerable uses for solenoidal wound coils.

Over the years there have been been hundreds of discussions and contributions to newsgroups about the Q of single-layer solenoid coils. But what is ENTIRELY missing is the measured data for particular coil dimensions and frequency.

Does nobody have a Q meter? It would appear nobody has any confidence in Q meters in the HF range.

QUESTION:

What is the measuring accuracy of the best commercial Q meters in the ranges of 1 to 100, 100 to 500, 500 to 2000 and above?

Or do not manufacturers state measuring accuracy? Are they themselves uncertain of what its all about?

A subsidiary question is what use is made of Q values after a measurement has been made? Does an inacurate Q value matter very much anyway?

Please give numbers in your reply. For once I confess to a minor troll. But I hope I get a few sensible answers to sensible questions.

Nil answers will be considered to be of equal consequence to the others.

A visit to the kitchen supplies of your local department store will
reveal a large assortment of coil forms and covers. Until recently I
have limited my antenna work to vhf-uhf. In that circumstance I have
frequently punched a snug hole in a plastic container bottom and
placed it in a bell shaped fashion over lumped LC components. It has
worked best for me to leave the bottom open for ventilation.

I have not done it yet but preliminary plans for a base loaded 160
meter vertical have me considering an inverted plastic garbage can as
a weather shield. The EZNEC models may spare me the effort on that
one!

Go to Home Depot, or equivalent, and buy 500 feet of wire the same color as your house. [Helps keep things invisible]

Run a loop under the eaves all around the house. Bring the ends of the loop to ground level. Electrician staples with insulated facing will hold the wire in place.

Feed the antenna at ground level through a small auto tuner similar to the ICOM AH-4, or one of the SGC units. Feed the Rf and control wires from the tuner into the shack through a window sill or equivalent.

When finished, you will have a small box on or near the ground, hopefully on the back of the house, and two nearly invisible wires from the tuner to the loop.

An alternative feed is to use end feed against a ground rod driven into the soil. An advantage here is that ground wire radials can be added to the rod and stapled below the grass line for a good counterpoise.

==========

Roy, you seem to have forgotten proximity effect.

If one calculates the Q of a coil from HF skin resistance of the wire and from coil inductance, one gets ridiculously high values of Q.

Other producers of coil calculators appear to have forgotten this too. That's if they were ever aware of it.

I have a coil, about 4 inches long, about 1.7 inches in diameter, with about 90 close-wound turns of 1mm diameter wire, which has an inductance of about 100 micro-henrys. The measured value of Q at 1.9 MHz is about 240.

This makes the proximity effect about 3.5 or 4 times the effect of simple HF wire skin resistance. This is a large amount.

This is the first time such information has been appeared on a newsgroup or published in bibles anywhere else. They didn't have Q meters 120 years ago, in Heaviside's time, when such factors were first considered.

My findings are incorporated in program SOLNOID3 which estimates Q (and other characteristics) for coils of various dimensions. There are, of course, other factors which influence Q which is a relatively unimportant coil characteristic.

What do you do with Q once you have taken the trouble to find it? The other more important things will already be apparent.

One possibility would be the sort of standoffs which have
traditionally been used to support runs of 300-ohm twinlead. They're
something like a long-shafted eye bolt, with a plastic insert in the
center of the eye to hold the twinlead away from the metal. Some of
these are intended for mounting on a metal strap on an antenna mast
(these have machine threads on their shaft), while others have a
wood-screw-like threading and a sharp point and can be screwed into a
wood beam. You'd probably want the latter. Radio Shack still sells
'em (15-853, $2.99 for a set of four) and they're probably available
elsewhere as well.

Another possibility would be to use short pieces of PVC or fiberglass
tubing, mounted to the eves using one- or two-screw conduit brackets.
4"-6" pieces of 3/4" or 1" PVC tubing, with 1/4" holes cross-drilled
in one end for the wire, then primed and painted to match your house's
color scheme, might be cosmetically-acceptable.

I just purchased an old Boonton 160A Q meter that seems to still be working, correctly. It supplys test waves from 50kHz to 75 MHz.

It was made in 1949 (the same year I was), is a 3 tube design, including the supply rectifier, and probably last calibrated when I was wearing diapers, but everything on it still seems okay. I have been using it to compare different coil and ferrite rod designs to improve my ability to build optimal rod antennas.

> QUESTION:
>
> What is the measuring accuracy of the best commercial Q meters in the
> ranges of 1 to 100, 100 to 500, 500 to 2000 and above?

Absolute accuracy is hard to quantify, because the connection losses, radiation losses and near field losses vary a lot, depending of the setup. The 160A has made a valiant attempt to have a low loss tuning capacitor available to resonate the coil at various frequencies, but if I pad this with an external capacitor, I never achieve as high a Q reading as I do with just the internal cap. The best I can do is compare variations with a single setup. In other words, if i can make two tests with a single setup, I can clearly tell which variation has the higher Q. But if I sit closer or further away from a large coil, it changes both results. At high Q, very little things count a lot. Measuring a large coil that is 6 inchs from any metal surface, and then putting it in a metal box, an inch from the side, kills the Q, anyway.

The scale on the 160A ranges from 20 to 200, but you can double that with another setting that cuts the excitation. However, at Qs above 100, the tuning is so touchy that I often can't find the exact peak.

> Or do not manufacturers state measuring accuracy? Are they themselves
> uncertain of what its all about?
>

> A subsidiary question is what use is made of Q values after a
> measurement has been made? Does an inacurate Q value matter very much
> anyway?

For tuning and filter purposes, it predicts the bandwidth. For rod antenna purposes, Q gets into the region of space the antenna couples to. The higher the Q, the larger volume of space the antenna pulls energy from.

I have also had some success at low frequency (below 1 MHz) measuring tank Q by driving the tank through a 10X scope probe, and measuring the resonant voltage with an AC volt meter through a second 10X scope probe. I find the frequency that produces the peak voltage, then tune up and down to find the two frequencies that produce .707 of that peak. The Q is the square root of the product of those two frequencies divided by their difference. I don't know if it is the loading effect of the probes, or lack of calibration for the Boonton, but I consistently get lower Q by this method than the Boonton shows. The Boonton may be 1.2 to 1.5 times higher. But, at least both methods allow comparison of variations, so I can have a "getting warmer" indication of which variations are better.

I have used insulated cup hooks screwed into the wood through
which I ran a loop of solid insulated wire. Both cup hooks
and insulation are available in a number of colors.

To extend from Ian's remarks:

In some critical applications, the use of coax cable with braided outer Cu conductor can cause problems.

RF charge flow (current) in the braid experiences a non-linear circuit resulting in harmonic distortion or IM or both. Just made coax can have a very low level of non-linearity with the effect increasing with age (and probable corrosion). Ag plated Cu braid seems to have less of the non-linear effect - perhaps because of a poorer mechanism for current to move from one wire to another.
The effects are small, but can be important in certain applications.
Solid Cu outer conductors have advantages beyond mechanical and power-handling.

These results were from Reg's c_poise program. The band is 75 meters and the coils were about 70 uH. The coils were a relatively large diameter, on the order of a meter. The wire lengths were about 20 meters. By varying the length the coil, the coil wire may be varies from 1mm to 12mm.

I have considered the same idea, however my soffit, fascia and eavestrough are all metal, and not electrically connected to each other. Does anyone have any suggestions on how far below these I would have to string my wire?

I have also considered bonding both the individual sections of each, and bonding all three together; but I'm not sure how successful such an attempt would be.

I ran a loop on the roof using plastic 35mm film containers as standoffs. I see no reason why you couldn't hang them under the eaves. A small dab of silicone seal was sufficient to glue the bottles in place. I used a soldering iron tip to put holes into and out of the bottles and strung the wire through them. My downlead was light 300 ohm twinlead. The antenna worked well and was up for a few years. A simple firm pull removed the bottles when I moved and didn't leave any damage on the shingles.
I didn't worry about things like radiation angles, radiation resistance, UV deterioration and all those things that can drive you nuts if you think about them long enough -- I just worked loads of stations and had a pile of fun.
It's cheap and simple.

I used pill bottles that were about three inches long. This placed the wire
about 2-1/2 inches above the shingles.

In my quest to understand Smith Charts better I ran across a very interesting site at Agilent
http://www.educatorscorner.com/index.cgi?CONTENT_ID=2482
Unfortunately, it would not work since I did not have Java on my machine. A little Google time later, I located the necessary free download (after reading of legal maneuvers) and installed it. Then the link worked fine. Nice site, very helpful.

Since they offer a free download I thought it best to capture my own copy of this for the future. After I download & unzip it, it does not want to function from my machine. I would rather spend the computer time with antennas rather than trying to figure out this computer puzzle. Anyone have a SIMPLE solution?
TIA,
John Ferrell W8CCW

Just downloaded it and it works without any problems. Do you
receive any error message? What do you see at the bottom of the
"SChart.html" file (which is part of the ZIP-File), where the
Java-Aplett should appear?

That sounds like a good idea - and I have used pvc forms myself.
I wonder if ecasing the coil in that 'Great Stuff' spray foam would be ample
protection ?

Hi John,

I unzipped all the contents into a dedicated folder.

I double-clicked the file SChart.html located inside the dedicated
folder. Works fine for Firefox.

Source record: 64249

John, thanks for describing your detailed and recent interesting experience and your thoughts on the subject.

However, once again the question is raised - how does one calibrate a Q meter? Rhetorically, is calibration traceable to National or International Standards?

So much depends on the Q quality of the meter itself. Meter manufacturers are unable to state degrees of accuracy at various frequencies and actual values of Q. Nobody knows what the actual value actually is! Least of all the user!

Fortunately, the exact value of Q of a coil is never required. It is used only to provide coarse estimates of other quantities. And there are usually other means of finding the other quantities. They can be estimated by calculating from values which CAN be measured or estimated.

So Q meters provide support and back up for experimenters who have other means of finding the answers they are looking for. By itself a measured value of Q is inaccurate and of no use. What matters is what can be derived or guessed from it.

It is merely an intermediate variable in a chain of deductions or calculations. Above Q equal to a few hundreds it is anybody's guess.

In some ways it is similar to an SWR measurement on a line which isn't there.

Reg.

How does the PVC's dielectric constant affect the antenna? Is there a
lot of loss?

I haven't tried that program, so don't know what it's for...
But... 70 uh is not far off from the usual inductance
needed to match a 80m mobile antenna. When using
Reg's "vertload" program, which I use for designing mobiles,
I don't see near the spread of coil loss that you see in that
program.
In vertload, to make that large a coil using 12 mm wire,
the coil diameter has to be fairly large just to be able to
fit enough turns in the appx 12 inch height I allowed for
the coil. But when comparing a like coil using 1 mm wire,
and the same coil using 12 mm wire, I only saw about
1 ohm difference, not 5. I'm not sure which is the most
accurate, but so far my real world results in mobile
whips seems to jive pretty well with vertload. I've made
a few coils with pretty thin wire, and had good results
as long as the turn ratio was ok. Ditto for fatter wire coils.
I made one that was 12 gauge and could see only a small
difference from one made with 16 gauge wire. Seemed to
shrink my bandwidth very slightly.
So...Dunno..Would have to do some tests to get the real
lowdown on the differences in loss I guess. But with the
mobiles, I came to the conclusion that real thick wire was not
really needed for a good coil, as long as the winding ratio
was right.

8214 is a Belden part number for an RG-8 (0.405" OD) type cable. So
if you buy 8214 you get Belden quality cable.

RG-213 is a generic part number for the same sized cable supplied by
any number of suppliers, some good, some not so good.

If it is a good supplier, then there is no difference between them.

If the soffits are not metal, they will probably be dry and just about anything will do for an insulator/standoff.

When you said "eaves", some of us assumed you meant under the lowest edge of the roof. Technically, eaves are the under part of a roof that hangs over a wall. So the overhangs at the ends of a gable roof are also called eaves. An inverted vee at one of the ends, fed in the center, would be something to consider seriously if you have a gable roof. The center would be perhaps 18 feet above ground.

On the other hand, if you have a hip roof, then a wire under the eaves will be entirely horizontal and approximately eight feet high. Such an antenna will exhibit a near-vertical radiation pattern and it will not be much of a performer for DX on the HF bands.

Good luck

Chuck

> However, once again the question is raised - how does one calibrate a
> Q meter? Rhetorically, is calibration traceable to National or
> International Standards?

Q is the ratio of two values (and several different pairs of values can be used to arrive at the same end result). For a coil, one ratio that produces a value of Q is the peak energy stored during an AC cycle to the total energy dissipated during a cycle. If you can measure those two quantities, separately, you can calculate Q. But it is often much easier to work with a resonant tank and use a capacitor that is known to have a much higher Q than the coil being tested, so that you can assume that all the losses are in the coil. Then the tank circuit Q is the coil Q. This is the bases of the Boonton 160A and also the signal generator, voltmeter method I have been using.

> So much depends on the Q quality of the meter itself.

The meter quality has to be higher than the Q of the device being measured, of a compensation has to be made for the meter losses. For instance, with the signal generator voltmeter method, I have calculated the losses in the two 10X probes, to prove to myself that the errors they cause are not significant up to the highest Q values I measured, this way. I would have had to measure a Q near 1000 before they would have altered a significant digit of the measurement. But I did convince myself that energy absorption outside the coil in surrounding objects is significant, since shifting my position in my chair did change the measurement.

> Meter
> manufacturers are unable to state degrees of accuracy at various
> frequencies and actual values of Q. Nobody knows what the actual
> value actually is! Least of all the user!

Boonton originally sold Q standard coils (inductors with known Q) to be used to check the accuracy of the Q meters. I don't know how those coils calibration got back to basic measurements traced to the Bureau of standards.

> Fortunately, the exact value of Q of a coil is never required. It is
> used only to provide coarse estimates of other quantities. And there
> are usually other means of finding the other quantities. They can be
> estimated by calculating from values which CAN be measured or

> estimated.

I agree. Usually, proving that a given device has at least a certain
Q is enough, or tests made on various devices by the same method can
show which ones have higher Q than others. This is what I am doing
with the measurements.

> So Q meters provide support and back up for experimenters who have
> other means of finding the answers they are looking for. By itself a

> can be derived or guessed from it.

Q is a way to measure losses. If losses are important to the
application, Q is one way to get information that is useful. An
infrared thermal imager may be another.

>So much depends on the Q quality of the meter itself.

Hi Reggie,

The "Q of the meter?" What a hoot. Would that be the impedance of
the handles over the resistance of the cover?

Let's also observe the Madison Avenue flair: "Q quality...." Or are
we to believe you are a proponent of measuring the Q of quality? Think
Lord Kelvinator would want a number put to it?

>Nobody knows what the actual value actually is! Least of all the user!

Let's see, if the user picks up an Ohmmeter to measure a resistance,
he doesn't initially know the resistance, he doesn't know the
accuracy, hence the meter is invalidated for existing, the user
suddenly lacks a metaphysical basis for being and all disappear in a
cloud of doubt.

>Fortunately, the exact value of Q of a coil is never required.

Now that meters no longer exist, users have evaporated, exact Q is
never required, the coil unwinds itself in existential abnegation.

>It is used only to provide coarse estimates of other quantities.

Ah! But if "It" is unknowable, "It" offers nothing - coarse or
vulgar.

>And there are usually other means of finding the other quantities.

Which then loops this logic back to the impossibilty of knowability
and these quantities suddenly dematerialize from the cosmos.

>They can be estimated by calculating from values which CAN be measured or
>estimated.

Estimates can be made of estimates - um yas, indeed! Now there's a
authentic statement of clarity and rational self-determination. Would
it be inappropriate to appreciate the irony of your attack on accuracy
where your argument is so conclusively lacking - accuracy? ;-)

>By itself a
>measured value of Q is inaccurate and of no use. What matters is what
>can be derived or guessed from it.

An excellent summary. If it is inaccurate and of no use, we can use it to derive or guess something from it.

Thanx for the opportunity,

Source record: 64260

Frank,

Good morning. Let me start at the beginning. I have a loaded vertical on 75 meters. The combination of the antenna and ground measure about 40 Ohms at the antenna. The models all show such an antenna over a perfect ground should have a radiation resistance of between 3 and 4 Ohms. That says the antenna system is less the 10% efficient.

This then is a journey to reduce ground resistance. Attempts to add radials and wire mesh to the ground have had very little if no effect. This leads to Reg's c_poise model. It predicts a coil in the range of 60 uH to 90 uH tuned to a 2 meter by 18 mm 'wire' will have a total resistance in the 2 to 4 Ohms range.

Together this should result is a 8 Ohm system. The ratio can be directly inferred as an performance improvement of 5 to 1 or 7 db. This is worth some effort.

To answer your question the first step will be one coil and one radial. The objective is the get the antenna system close to 10 Ohms. From there I will experiment with adding radials and coils. I am not sure what to expect.

Thanks - Dan

Hi John,

And for the sake of trolling, Reggie claims he doesn't either.

Gads this is so simple as to defy the angst that surrounds this. Any good Impedance Bridge which reports R and X separately will give you the means to measure the Q (or D) of these standards. All this folderol of the "Q quality of the meter" is so much hokum distracting from a simple determination.

Balance the bridge and you will have the resistance that so impacts the Q. Balance the bridge and you will have the reactance that establishes the Q in relation to the resistive loss. And what does the meter have to do with Q? The bridge is adjusted for a zero reading! What accuracy statement can be said about reading zero when you return the needle to the position it was in when the unit was stone cold? THIS is how you qualify the standards Boonton offers. You then qualify your Bridge against separable quantities of X and R. For sure, this may relegate us to a tedious cascade of "how do you know what value those are really?" It is this kind of whining that leads to warning statements being forced into curriculums by those who want to teach Untelligent Design.

Reggie has managed to turn the discussion of Q into a mystical, unknown quantity impossible to determine by his simply ignoring first principles. You measure the Q of the unknown two ways and compare. By the Bridge and by the Boonton. I dare say no more than 20% accumulated error will occur with NONE of it attributed to the "Q quality of the meter" - whatever that is.

So, let's compare. You can have a determination within 20% of actual, and continue to design with confidence. OR You can mumble about the abstract impossibility of ever getting it abso-*&!#ing-lutely right and find yourself in analysis paralysis.

I have, of course, steeply discounted the accuracy of the Boonton to include all RSS accumulation of errors in the instrument's calibration. The manufacturer warrants the device to 5%.

Now, if you strip away all the numbers, you can re-achieve the distinction of the Qualitative statement that got us here. Lord Kelvinator would point out that that and $5 will buy you an insolated cup of Latï¿½.

NOW AVAILABLE ** New Program "OPANGLE3.exe"

Choose and set plate current operating angle for Class-B and Class-C
RF power amplifiers.

Input data includes control-grid plate-current cut-off volts, DC
negative grid bias, and peak grid drive volts.

Advice on how to use Tube Operating Characteristic Curves is included.
For interest the plate current harmonic content is computed up to the
21st harmonic.

For given DC plate supply volts and peak plate signal volts, the DC
power input, tuned load resistance, RF power output, plate dissipation
and efficiency are computed.

This is a repeat of program Op_Angle (now withdrawn) with the addition
of an analysis of conditions in the plate circuit.

Program size = 50 kilo-bytes.
Download OPANGLE3 from website below.

1554. 2m/440 antenna Q's

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-19 23:28:00 UTC
From: Bill Berris <wjberris@NOSPAMsbcglobal.net>
Message-ID: <4a7Kf.49300$dW3.14954@newssvr21.news.prodigy.com>
Source record: 64265

Hi there!
I am new to the group here, and have a couple of basic questions that I can hopefully get some help with...

I have recently decided to start becoming active on the air (VHF/UHF) again when I found my HT as my wife and I were moving into our new house.

I am pretty much restricted to the HT for a bit, and want to come up with a better antenna solution. A buddy gave me a mobile 2m/440 antenna and mag mount base that he used to use with his Kenwood TM-V7A.

Question 1 -- The coax coming off of the mag mount connected directly to the antenna feed line input on the mobile radio. What kind of connection is this? I need to get a cable that will transition from the antenna feed-line to the BNC connector on the HT. I would need to get this on a length of coax (or just the connections and make my own cable) so that it will reach the garage. Where could I find the cable and/or connectors?

Question 2 -- I was thinking of mounting the mag mount up on one of the rain gutters that is only about 8 feet off the ground... would the modest gain from the antenna along with the 8' mounting provive a significant improvement over a rubber duckie? Or, should I build a 2m J-Pole?

Thanks a bunch for any information you can help me out with -- I am looking forward to getting my feet wet again so that I can convince my wife that I need more radio equipment... :-)

73,

The connector from the feed line is most likely a PL-259 UHF plug connector,
since it's intended to connect to the (usual) SO-239 socket connector on a
mobile.
(No guarantees, 'cause I don't have that Kenwood.)

Check http://www.universal-radio.com/catalog/parts/so2adapt.html , one of
many, many
sources of connectors and adapters. You want a UHF Female/BNC Male adapter
if you
connect the existing antenna to your BNC connector on the HT.

Nearly anything is better than the rubber duck. They are a compromise in every regard except size. I don't feel totally warm and fuzzy about the rain
gutter thing, however. I think the needed capacitive coupling of the mag mount to its ground plane (the rain gutter, in this case) may not be adequate. Can you think of something slightly bigger ... and FLAT ... under that magmount? (I once used a steel TV tray and it worked fine.)

> Or, should I build a 2m J-Pole?

J-poles are great. I have built about two dozen J-poles, some for sale, some for
giveaway, some for our local RACES station and three I have in service here at home. (A 6M J-pole is 13 feet tall and I have built three of them, all from copper
water pipe.)

A 2M J-pole presents a satisfactory match at 440, so I consider it a true dual-band
antenna but its radiation pattern on 440 is mostly NOT toward the horizon, which
means somewhat reduced range on 440 compared to the range with a separate, dedicated 440 antenna.

Thanks to all you guys for enlightening me. I did an experiment
- I tuned the dipper to 146.520 (not easy to get it right there) and
took my HT out for a walk. I could hear the carrier out to about
400 yards! I'm in a wire mesh/stucco/aluminum siding structure
in the city so that kind of output from an instrument is surprising.

Imagine what it would have done if I inductively coupled to my GP-6
at 25' ? lol! Next I'll try it on HF with my K2....

1557. Usenet Kook Alert .... Lyle Blake

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-20 03:07:03 UTC
From: diannamelrose@gmail.com
Message-ID: <1140404823.199601.294020@g43g2000cwa.googlegroups.com>
Source record: 64268

The person posting here as "dot" with an ISP at sympatico.ca is a truly viscious Usenet kook who is currently harassing 3 other newsgroups.

This man's name (it's not a woman) is Lyle Blake and he recently claimed on another newsgroup that he had a bamk of lawyers ready to sue the Amatreur Radio society in Canada because they would not grant him a HAM license test (hint: he's on a psych disibility and can not afford lawyers)

Lyle has appeared in several other newsgroups in the past (although he specializes in trolling transgendered ones) such as the pascal and Delphi programmers newsgroup.. He strives to create (short term) havoc on newsgroups by making overly nonsensical claims and causing flame wars.

He initially presents as "supportive" to new group members which is used as a ruse to eventually engage people - usually transgendered people - in flame
wars.

In a short while you may notice a rash of odd postings regarding black people (he uses the "N" word) and anal related postings - those are Lyle's trademarks.

Lyle specializes in harrassing people in transgendered newsgroups. He is unemployed,lives off a psychiatric disibility welfare check and spends
all his time (24x7) on Usenet.

He has claimed to be everything from a TS to a TG to what he calls a "male-woman" and now claims to be an androgyne. Basicaly he is a certifiable idiot.

Here he asks a white supremacy group to troll a Usenet groups:

http://groups-beta.google.com/group/alt.support.crossdressing/msg/90a...

More info about him can be found in this FAQ - read it and decide for yourself about him:

http://groups-beta.google.com/group/alt.fashion.crossdressing/msg/9d1...

And this is what the little creep looks like:

1559. Re: using coax shield to create a loading coil ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-20 03:20:01 UTC
From: Frank's Basement 2 <francis@carolyns-creations.com>
Message-ID: <BzaKf.5666$_62.1492@edtnps90>
Source record: 64270

Hi Dan, thanks for the interesting info. You did not specify dimensions, but from your comments it appears you are using a vertical about 23 ft high. Such a monopole would have a 3.5 ohm input impedance when placed above a perfectly conducting ground, and gain about +4.5 dBi. Adding a center loading coil raises the input impedance to 11.5 ohms, and gain +2.6 dBi. Base loading provides an input impedance of 5.5 ohms with almost the same gain as center loading (Q = 400). Adding ten, 6ft radials, at 3" above an average ground, the input impedance increases to 40 ohms, and gain -6.3 dBi.

Adding lumped element loading coils, (75 uH, Q = 400) in each radial (antenna base end) drops the input impedance to 37 ohms, and gain -6.4 dBi. Don't know why this does not agree with Reg's program. Probably I made some fundamental error with the NEC model. Included the code below, so you may see an error I missed.

73,

Frank

Hard to beat Davis BuryFlex which besides being very low loss (nearly the same as 9913 within a couple tenths of a db) is direct bury and has a 20 year service life.
Got nearly 500ft of it here on all my antennas from HF thru VHF

Frank,

Thanks for the model. I did not expect you to model this or I would have been more specific. The antenna is about 14 feet. The coil is about 4 feet from the base.

Now the radials: Did you base the radial from Reg's model? Try 3.97 MHz, 1 meter above ground, 3 meter radials, and a 60mm long by 300 mm dia 66.7 uH loading coil. These grounds have to be tuned as well.

I am using 4nec2 and am getting errors from the GM card. Wasn't there an issue with these being a decimal instead of an integer?

BTW - The simulation on my laptop takes over 5 minutes to run.

Dot will need to make postings a lot nastier to be considered by most to be "a truly viscious [sic] Usenet kook." HIs post seemed ordinary enough.

However, will watch for incipient flame wars and take kill-file action, as needed.

Follow up:

One of the not so apparent results of Reg's program is the relationship of radial length to height. I chose 2 meters because they were only .7 meters high.

I raised your model to 2 meters, that reduced the R to about 20 Ohms. Raising it to 3 meters lowers it to 18 Ohms.

How did you calculate the H of the loading coils? Is that easy to edit? It would seem that these values are closer.

I see the length is set to 1.8 meters already. A 2 meter elevation minimum is needed to lower ground effects.

How is the lumped inductance set of 4 Ohms and 1750 Z? What impedance does that translate to? How did you calculate this value? Dan

1565. Low power 5w FM Transmitter antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-20 07:20:29 UTC
From: samuel.lawrence@optusnet.com.au
Message-ID: <1140420029.713791.128680@g47g2000cwa.googlegroups.com>

Hello,

A friend of mine live in outback NSW and wants to install a 5w FM Transmitter on his property to transmit music between buildings - 88 - 108mhz - can anybody suggest an antenna for this purpose - maybe a link to manufacturer/distributor in Australia? Yes we understand that it is most probably illegal but think that signal will not drift off property.

Thanks in advance.

And it works fine using Camino on my G4 PowerMac. (Camino is rather like Firefox, but it make direct use of Macintosh system calls and thus is much, much faster than Firefox.) I had the thing working about 3 seconds after downloading it. Java is Java is Java and should be completely platform-independent. But if the original poster is using Internet Exploder, that may the be problem. The mozilla.org browsers are safe, they have Java built-in, and anyway he should replace IE with Firefox for his computer's health's sake and not just to make Java work in the browser.

Hi Sam

Keeping this technical rather than legal!

I think the cheapest/easiest way to do this is mount a quarter wave whip on top of one of the (many?) corrugated iron building roofs.

There are many ways to start this off. I guess that given proximity of resources etc a cut down CB mobile base and whip would be a viable option. I am talking about a fibreglass or stainless steel antenna that initially would be about 9ft to start with.

The length of the whip would be roughly 300/freq/4 but tuning it with an SWR measuring device would be a good thing to do.

Cheers Bob VK2YQA

It also fails to run as a download from the XP Home Laptop (also IE 6).

I need to run the most popular browser so that I can verify the operation of the web sites I maintain and to stay familiar with my client's configurations. I used to keep Netscape available to verify anther browser but have opted for a Linux (USE 10) machine as an alternate lately.

It is unfortunate that Microsoft has elected to shun Java but I won't let that become my problem.

Thanks for all the help, I choose to outflank the Java issue and get back to the Smith Charts!

Dan,

I find antenna problems very interesting, so do not mind spending time on running models.

The radials were based on your comments in an earlier post about "2 meter radials". You have provided me with a lot of information in subsequent posts, so will use that info to try and construct a more realistic model. I still have a couple of questions though: how many radials are you using, and where do you position the radial loading coils?

You are correct about the "GM" problem, and I forgot it produced an error in 4nec2. The last "ITS" field should be an integer. I have not completely confirmed it with 4nec2, but the ITS field refers to the tag to be replicated -- in this case tag 2. GM generates 9 tags rotated by 36 degrees, and saves a ton of GW cards.

I cannot understand why your simulation takes 5 minutes since there are only 184 segments, and 11 frequencies. I just checked and it takes only 3.9 seconds with my NEC2 program, or 4nec2. Anyway my model will take a lot of revision to replicate your actual antenna. May get a chance to look at it later tonight.

73,

Frank

you can use two transfer switchs
+ 2 coax jumpers to conect them,
but most transfer switch are using N connectors
i can do schematic diagram if you need

Dan, even more questions: I don't understand the relationship of radial length to height. c_poise seems to allow anything. What is the "H" of a loading coil?

Frank

Everything is wood

When you said "eaves", some of us assumed you meant under the lowest
> edge of the roof. Technically, eaves are the under part of a roof that
> hangs over a wall. So the overhangs at the ends of a gable roof are also

its going to be a loop and the location you describe is accurate

I just wanted to know what the best way to hang this wire from the eave is.

1573. Re: using coax shield to create a loading coil ?

Dan,

The lumped inductance of 4 +j1750 comes from your previous comment about the inductance range from 60 - 90 uH. I just chose the mid range value of 75 uH at 3.8 MHz. To be exact 2*PI*f*L = 1791 ohms. The real part of 4 ohms is based on an approximate Q of 400.

Incidentaly I am working at another location this morning. The computer is an old 600 MHz machine, with 384 MB of RAM, and Windows ME OS. The NEC code here takes 17 seconds to run.

73,

Frank

a simple receiver antenna will do fine.
Just don't use a amplified antenna.
With 5Watts a simple 1:4 ferritebalun in the connectionbox will do the coax
to foldeddipole match too.

Dan, here is a preliminary run on a 12 ft monopole model structured as
follows:
base at 6 ft, 10 x 6ft radials. All #14 AWG. Ground - perfect, frequency
3.8 MHz.

Zin = 0.968 - j1847.55 ohms;
Efficiency = 87.4 % (structure copper loss);
Gain = 4.15 dBi;
Take-off angle = 0 deg;
Gain at 27 deg elevation (expected TOA with real ground) = +3.09 dBi.

I will try successive modifications to approach a practical model. The code
I used, modified so it should run in 4nec2, is shown below.

73,

Frank

```
CM 75 m Vertical 12 ft high
CM base 6 ft up, 10 X 6 ft radials
CM copper conductivity
CE

> eves of your house.

But staples are metal, which might compress the wire against the wood and damage the wire. Not sure if the staples being metal would effect anything but it I was hoping someone had some experience with this kind of setup.
I was thinking of stapling a black UV resistant cable tie every 10-15 ft and running the wire thru the loop made by the cable tie. Actually a bad idea I think.
Someone did mention the screw in type tv cable standoffs. Thats a possibility but I guess I am looking for someone who has actually done this to see what they had done and what problems they had encountered.
Another poster also mentioned it would be a poor DX antenna, maybe, as my house sits on sloping ground and is post and pier the eaves are over 25' on 1/2 of the house. This could be a decent antenna for maybe 15 & 10 meters.
But in my original post the idea was to be used as a receiving antenna maybe for transmitting on 40 & 75 locally.
One point I do want to make again - the other half wants me to make sure its as eye pleasing as possible, which means it cant be easy to see.
When I first thought about doing this I never realized it actually required as much time to come up with a solution as it has.
Simple project? You and I would have thought so.

1578. Re: Low power 5w FM Transmitter antenna

Newsgroup: rec.radio.amateur.antenna

Dunno if I'd go the ferrite path. If you dont know the material it may
just end up saturating and being radiated as heat! I'd suggest a
frequency dependent match like a 4:1 coaxial balun if you want to use a
folded dipole. Thats just a 1/2 wave length of coax at the right freq
allowing for velocity factor. Lots of places to search what that looks
like on the web. try;

http://n-lemma.com/calcs/dipole/balun.htm

You could use a ferrite balun especially if you are looking for
broadband use. Take care with material selection and wire turns though.

Cheers Bob

http://www.ramseyelectronics.com/cgi-bin/commerce.exe?preadd=action&key=TM100
is a pretty good antenna for low power transmitters. It's pretty simple to
build too. If you're any good at interpreting the assembly instructions,
you can probably build one from scratch. The instructions are at
http://www.ramseyelectronics.com/downloads/manuals/TM100.pdf. Mostly made
of common PVC piping and hardware, and the innards from a 300-75 ohm TV
transformer, and a ferrite core.

Frank,

Good morning. I had a few minutes and created the following model. It is shortened and the number of segments in the vertical is increased. I also set the inductors to 3 Ohms. (That may be optimistic for the antenna, Reg's program predicts 2 Ohms is achievable for larger coils on the radials.) (Sorry for the long numbers.) This shows a resonance at 3.9 MHz and 9.9 Ohms.

4nec2 did not like the GM card, I did not remove it.

Dan

Frank,

I tried the nec below. The result was resonant at 21.9 and about 34 Ohms. I am not competent at reading nec cards yet, however the model editor does not show any coil loads. That could explain the frequency?

Dan

Thanks - Dan

I missed this one. About 96 uH.

RE: STAPLES

Electrician Staples are INSULATED.

Look into these: "BRISCON Insulated SN 40".

They are 1 inch long and 1/2 inch wide.

I've used them for years in a WX protected location.

stananger wrote:

If you keep thinking and talking about it until you
have a perfect solution, it will never get done. :-)

Source record: 64197

Hi Dan, I tried your program, it runs fine, and I get identical results. I also learned a couple of things from your code: Setting "GE" = 0 implies no ground plane present (I would normally set it to "1"), and my "Nec Vu" function shows the antenna with no ground plane. Running the program, however, returns the correct result with an average ground.

I also ran the program with no radial loading (code below), and the gain increased marginally. It seems loading the radials does not help much.

Frank

1587. Looking for aluminum tubing/rod in DC/MD area

Newsgroup: rec.radio.amateur.antenna

I'd like to design and build a new 2-meter Yagi antenna, and would like to construct it using aluminum tubing and rod. Drawn tubing--the stuff with an axial seam--would suffice.

Anyone know of a good source for this stuff in Washington DC or nearby areas in Maryland? I've tried Home Depot and the like, but the stock available in these places is incomplete and expensive.

Forgotten? I just didn't see what relevance it had on the difference in Q between an inductor made from a braided coax shield and one made from solid tubing. And I can't see from your posting anything which adds to that discussion. But maybe I'm missing something?

I wouldn't over think it too much. Try just a floppy wire 18 inches or so,
and see what noise it picks up? You're bigger problem is those radios
aren't designed to pick up distant stations, so outside of a large metro
area you might not get any reception, or worse a signal that constantly
fades in and out. Try the simplest solution first, then start adding
pieces.

1590. Fiberglass roof on FJ-40

Newsgroup: rec.radio.amateur.antenna

Howdy Y'all:

I have a fiberglass roof on my Landcruiser, and I was wondering if I can use a halfwave roof mounted antenna?
For some reason, I think since the halfwave is end loaded, that it will not work on my fiberglass roof, and that
it uses a steel roof as part of the match. Am I wrong here? The only other thing I can think of is some kind of
stainless steel J pole on a mount coming off the back. And what about a dual band that will work on fiberglass?
Anybody work with this problem before?

It has been a while since I measured the 3db points of a inductor, but I
think the probe did load the coil. I recall putting a 1meg resistor in
series
with the probe to help isolate the probe capacitance from the inductor.

Any Q measurement of a tuned circuit must pull less energy from the tank than the tank consumes each cycle, if the meter's effect can be neglected. The Boonton 160A injects a voltage into the tank with a fraction of an ohm source impedance. And a vacuum tube volt meter measures the resultant voltage across the tank. Both these paths represent a loss, and limit the highest possible Q reading to about 400. But some tank impedance combinations (very high impedance affected by volt meter input impedance, or very low impedance affected by voltage source impedance) may face more severe limits.

I bridge type measurement can be zeroed for its internal losses before the measurement, so is more self compensating. But any equipment I have seen will have trouble accurately measuring extremely high Q tanks, inductors or capacitors.

Source record: 64207

On mine, I mounted a telescoping BC band replacement antenna at the top of the metal body piece just behind the door and collapsed it down to about a quarter wave on 2 meters. Although you could probably fiddle the antenna length to get a fair match, I built a little highpass T network out of an inductor on a small powdered iron core and a couple of trimmer capacitors to do the matching. The pattern is probably pretty skewed, but it's adequate to reach the local repeaters. You could mount a dual band antenna at that same spot with some sort of right angle mount.

A half wave antenna at the top of the roof should work ok, but even with a half wave antenna, there's a small amount of return current that has to go somewhere. If I were willing to punch a hole in the top (which I'm not -- have you seen what a replacement top costs?), I'd do something like put a small ground plane inside the car against the top.

This might be a reasonable application for a through-glass antenna -- through one of the windows, that is, although it might be interesting to see how one would work as a through-the-top antenna if you could rotate it to be vertical. But having spent quite a few hours studying various patents for their design, it looks like some might work much better than others.

Probably the gutter is made of aluminum if put up in recent years so that won't work. Put a dual band mobile on a 6"X6" sheet of thin steel and make four radials about 16" and bend them down at a 45 degree angle from the corners of the plate. Mount them to the steel plate with small bolts and nuts. Put the whole thing in the corner of your room. Unless you are in metal building the antenna will work about as well as it would outside... and yes it will be light years ahead of a duck.

That's correct Dan. I just wanted to systematically build up the antenna, adding a component at a time, to note where the major losses are. This was the first trial with no loading -- except for copper conductivity.

From the other model you sent me it seems that any other attempts are redundant. The major losses are due to ground loss, as expected. Unfortunately this can only be overcome by increasing the length, and number, of radials -- something that is pretty well known. Also inductive loading of the radials does not seem to have any effect, except for marginally decreasing the antenna efficiency.

I have been interested in installing a short monopole for 160m, so am very interested in your results. I have a fairly large lot (visible on "Google Earth), so am not so restricted in radial length.

73,

Frank

1598. Re: using coax shield to create a loading coil ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-21 04:56:08 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <43FA9D68.3060807@comcast.net>
Source record: 64210

The effect of the radials is a surprise. I would not expect that short radials would work well at all? The system predicts about 9 Ohms. That is closer to what is expected and over 6 db better then the 50 Ohm reading.

I will try experimenting and let you know.

Thanks - Dan

Back in the '50s or '60s there was a book published wherein the hero was trapped or something and called for help by sending CW with a grid dip meter. Don't remember any details but it was a great read when I was a teenager.

Thanks for the info... the portability of the design (and the design Dot
posted) look great... I will probably try one of those and maybe something
like this in addition --> http://www2.arrl.org/tis/info/pdf/0302038.pdf

What do you guys think of that one?

Totally plausible as I have noticed when I tune a FM receiver
to my dipper's carrier, I can deviate the carrier with my voice
if I get close to the case of the dipper. Found that out the other
day when I turned up the volume on my HT and got a squeal
from the dipper!

Now when I'm searching for the carrier and my scanner stops
on a signal, I tap the dipper's case with a coin and not only do
I hear it quite clearly on the scanner but it sounds like a mic
in a coffee can. Helps to differentiate between birdies and my
target carrier.

Love it!

Ken KG0WX

If there is an Al extrusion plant nearby you can try them. I used to
get it from an Alcoa plant for scrap prices.

Back in the sixties I was living on a postage stamp sized lot in the city and working 2M EME.

Some W6 moved to the next street over and decided what Tucson needed was his crappy 2M repeater on the air.

Shortly after he moved in, while I was on the air, the next door neighbor calls and said that I was creaming her TV. I hadn't changed anything in months, but nevertheless began a witch hunt for my problem. After a fruitless search I decided that maybe it was the repeater and not me. Not owning an FM rig, I needed another way to bring it up and thought of the GDO.

Swish swish and up it came (but with no TVI). It took more detective work to figure out that it took my signal being on the air when the repeater transmitted to clobber the TV. I let my automatic keyer run the transmitter while walked next door to the neighbor's with the GDO and went swish swish and the TV choked. I guess his receiver wasn't up to handling 100KW erp a couple of hundred of yards away. [g]

1609. 20 Meter Dipole - instant DX!!!

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-21 16:35:32 UTC
From: Radio TexMex <ke5ckrIGNORECAPS@gmail.com>
Message-ID: <dK-dnaQIc_uG3GbeRVn-iA@giganews.com>
Source record: 64221
Cross-posted to: rec.radio.shortwave,rec.radio.amateur.antenna

For the last 6 months I've been using a 1/2 wave 40m dipole sloping from an oak tree in the back your to a peach tree in the front. This has worked great for 40. I use this for amateur activity as well as SWL stuff with an MFJ tuner. I always noticed that on some bands, particularly around 20 meters, I couldn't receive as well I thought was possible. The closest thing to DX I've worked was a station in Costa Rica.

Well I finally got around to stringing up a simple 1/2 wave dipole with a 4:1 balun, cut just for 20 Meters. I strung one end from the same point the in the oak tree that my 40m dipole uses but I wanted to keep them angled at least 95 degrees away from each other to keep them from interacting. Because of this, I ended up sloping this fella down into the backyard between the oak and another tree and tied it off to a martin house. I was worried about the fact that I couldn't position this dipole any better away from the trees - and/or higher.

I finally got a chance to try it out yesterday after all the above ground power line noise dyed down, and wouldn't you know it, ACTIVITY EVERYWHERE on 20!!! Way more than I'm use to hearing with my 40m and the tuner.

The 3rd station I worked was in Serbia!!! And I can only squeeze 50 watts out of my Yaesu FT101B on 20m.

Moral of this story: I've learned you can only get so much performance out of an unmatched antenna with a tuner.

Cheers! - Matt

> I am using 4nec2 and am getting errors from the GM card. Wasn't there an issue
> with these being a decimal instead of an integer?

Yes, it was and still is. 'Original' Nec2 does not understand the
Necwin+ syntax for the last field in the GM card when the 'x.y' format
is used. Within (modified) Necwin+ the ITS (imov)field with the x.y
format does move all (preceding) wires with tags from 'x' up to tag
'y'.

With default Nec2 the x.y field is rounded to an integer and all wires
with tags from 'x' up to the one just preceding the GM card are moved,
so no explicit 'end-tag' is specified.

When using Nec4 one can specify both the start- and stop tag- and
segment-numbers on four separate fields.

Arie.

Understandable :)

This is how Lyle Blake alwas works ... just be sensbly aware.

I can tell you what he intends to flame about here - on another
newsgroup he is claiming that Industry Casnada is denying him the
ability to take the Ameteur Radio test because of his gender
presentation (he is makle but like to dress in woman's clothes). The
reality is likely that he is just to psycho to be able to arrange a
test date.

Here is an out take of what he is saying in other groups - just
forewarning you about it here - FYI:

FWIW - On another newsgroup he made (another) death threat against me
because I spoilt his "fun" here ...

My name is Michael. I'm educated as electronic mechanic. I started a project with the goal to receive and decode the VMS signals from Inmarsat. VMS system is manly used on fishing vessels. On the ship there is a box with a gps and satellite transceiver. The
position information is send each hour, to a land earth station, were it is distributed to the different authorities. I hope that many of you will help and contribute to get this working, because I don't have all the skills my self.

First I started to ask people in different news group about the subject. But I now realized that it will be a bigger task. So I have made a Yahoo group to get this thing going. I have in this group posted the information I have gathered until now. If you think you maybe can contribute to the project then, or is interested in this as well, then please join at

http://groups.yahoo.com/group/vms_group

Cheers Michael

Sorry, it's been nearly 20 years since I went through the patents, and I don't recall all the various modifications and innovations I came across. And I don't have any idea which might have been included in commercial designs. Surely someone has done some comparative measurements of various commercial units and published the results. If not, it sounds like a good project for someone interested in using through-glass antennas. I'm not one of them.

Hi to all.
> What's the correct designation for the Female ?

"UHF" feed lines are usually and commonly terminated with a 'N' Type plugs into a 'N' Type Socket.
"VHF" fed lines are usually and commonly terminated with PL259 plugs into a SO259 Socket.
The indicator, PL represents a Plug, and SO represents a Socket.

If you think of it in a bodily manner, relate to it as Male= PL and Female= So, and so a [male enters the female]
Take a look at any "UHF" transceiver and you will find that it's a 'N' Type socket on the rear entry of the rig, a far superior plug to the PL253/8/9 Etc Etc Series.

Dual band transceivers are terminated at the rear by a PL259 socket.
Hope this helps. Cheers Dave.

Before someone beats me too it, I've already had somebody point out the goofy flaw with my new super awesome 20M dipole. And after doing some much needed reading on baluns, I've concluded that the 4:1 balun isn't needed.

Readers: Please be patient. Learning process taking place here.

Reading about 4:1 baluns makes one imagine a 4:1 balun is
cessary - whereas most likely it isn't.

Glenn,

I suspect you just have a noisy environment. You probably need a noise machine such as the ANC-4 or MFJ 1026. You might also try a noise antenna such as a K9AY loop. I have one K9AY loop and it really helps pull them from the noise. I am fairly quiet on 80 but very noisy on 160.

First, 5W will likely go out 5 miles. I know because 100 mW will go beyond
1/2 mile, per my own tests. Please appreciate the interference potential
of that unlicensed 5W signal.

The ideal antenna for this is the folded dipole antenna, hand-made of TV
receiving twin-lead wiring -- the flat stuff, consisting of two conductors
having about one centimeter spacing. You make the antenna with that
leadwire
and you feed it with that same leadwire. You must NOT have any of it run
along
or against metallic material of any type. That's what stand-offs are made
for.

Have a look at http://www.wisegeek.com/what-are-fm-antennas.htm , especially
the dimensions in the second paragraph. Antennas are reciprocal; one that
works
for transmitting will work for receiving, so you build two. You can fasten
the
antennas to wood sticks for their physical support (essential for a medium
as
floppy and flexible as twin-lead).

Let us know how this progresses. (Makes the typing seem worthwhile.)

I see the actual construction details are lacking in the reference I
offered.
Then try this one, too:

http://www.kgnu.org/howtohear/antenna.html

Good luck.

Vehicle roof-mounted antennas are commonly quarter-wave whips. I know there are 5/8 wave whips but I am not prepared to address their use.

How flat is the roof? If it's flat enough to permit you to cement a sheet of steel to it, then use a mag-mount. I know the sheet of steel needs to be only about the size of a TV tray, since that's what I used and got a good match with an MFJ El-Cheapo dual band magmount. (I happened not to be using it on a vehicle roof; however, the TV tray made a satisfactory ground plane, anyway.)

My non-ham buddy used this basic method on his motor home roof for a magmount CB antenna that was much longer than the MFJ dual-bander. It never blew over and the sheet of steel never came loose.

So, can you glue/cement/bond/rivet/nail/staple/tape a 2-ft by 2-ft piece of galvanized steel to your roof? (Caution: Stainless is often non-magnetic.)

I love J-poles. I make them out of copper pipe but have no vehicle experience with them. The J-pole is a half-wave antenna that works great in free space and requires no ground plane.

More?

Might not the socket connector be called SO-239? I did a quick "Google"
before sending this.

You want an antenna, or a GPS receiver with antenna? Not sure what you'd need USB for, if you want just an antenna. (Most antennas with LNAs built in power the antenna amplifier from "phantom" power on the receiver's antenna connector.) -- If you want a USB GPS receiver for you laptop, I'd suggest you just buy one. You should be able to find one on ebay for around US$50, complete with built-in antenna and magnetic base.

A half wave antenna will work just fine. Several antenna manufacturers
make them for just the type vehicle you have, corvettes,boats etc.

Thanks for both your suggestions. Since my original post, I've attached a common-mode choke near the top of the open-wire feed with what seems to be excellent results (I originally wanted a sort of Windom action, but not on the noise!). I suspected, along with John, that some vertical noise components were getting in due to coupling from the vertical feedilne to the unbalanced feed on the dipole. The dipole now tunes as I expected it to originally, and S/N does not shift with tuning, as far as I can tell. By the way, the vertical open wire line runs up near the side of a three story high aluminum siding slab, and I wonder if that was a factor...

The antenna's noise has now dipped below my HF rig's (an old one--may need alignment) noise floor on several occasions, even on 40M. My main surprise from this activity was that antenna tuning affected the antenna S/N. I didn't know that happened.

David, your noise loop--I assume that's designed to receive noise and not signal, allowing a noise cancelling box to be of use, or is it visa-versa?

73,
Glenn AC7ZN

1640. Re: using coax shield to create a loading coil ?

Newsgroup: rec.radio.amateur.antenna

Dan,

Will be interested to know how you get on with the antenna. I suspect that adding loading coils to radials is about the same as adding loading coils to any part of an antenna system. They do nothing to effect the radiation efficiency, only modify the input impedance.

73,

Frank

Wherever did you get that idea? A dipole made out of
80m hamsticks is less than 1% efficient.

<sigh>
I've *removed* the crossposts from this message.
Lyle's stock in trade is to initiate crossposts between groups as well
as to bring on Usenet fringe groups to disrupt any group he wants to
....

In the message below he was caught (we looked at the IP address in the
message) attempting to incite posters in a a white supremecist group to
make trouble in a newsgroup he disagreed with. He also forgot to
switch newsreaders or whatever so his his signature line remained as
well.

Well, I guess I should have said: "... do nothing to effect the radiation
efficiency, except possibly reduce it".

Don't know anything about "Hamsticks", but they must have lousy loading
inductors!

Home Depot aluminum is very soft and weak and is not a very good material for antenna-building purposes. Use high-strength aluminum alloys like 6061-T6 or 6063-T6. McMaster-Carr is a good source for high-quality aluminum but they don't carry much of a selection of sizes. For ham antenna purposes your best bet is probably Texas Towers.

http://www.texastowers.com/aluminum.htm

Another route which I use is have a local friendly industrial machine shop or sheet metal shop on tap which will buy whatever you need from their established industrial metal supply houses and reimburse the shop for their expenses on your behalf. Usually there are no shipping costs involved and you can get full lengths of tubing vs. the cut 6' and 8' limits offered by TT and McMaster. Aluminum tubing comes from the mills in 12' and 21' lengths and can be simply cartopped home. The trick is to surf the Yellow Pages for a local indusdtrial shop which will work with you.

Or in some cases a private individual can buy metals directly from local mill supply houses which sell to the industrial shops. This is a workable approach but only in heavily-industrialized regions where a metals distributor is within a reasonable driving range. The DC area shuld "qualify". Back to the Yellow Pages under "metals" . . .

To be exact; a 16 ft dipole would need to be loaded with inductors of Q = 78
for a 0.99% efficiency. The gain is therefore -18.3 dBi.

Have you experience running 100w into one of these transformers
yourself? I kinda doubt they would take any watts.

If I understand you correctly you are talking about the little unit
that connects the cable to the old 300ohm input of 1970s type tv.
These units have very small toroids, only maybe a quarter inch in
diameter, that are designed for microvolts of excitation at the bottom
end of TV band - which is somewhere near say 50Mhz. They will not
handle any magnitizing flux and I would bet a watt at 20m would
overheat it.

Lee,

These are free-space antennas, intended for fitting with a length of coax terminated in the particular connector that mates with the connector on your GPS rcvr. My Garmin GPS-III takes a BNC and I have my patch antenna mounted on my van's luggage rack; Eight feet of coax brings the signal inside.

Not familiar with the 310 -- are you looking for an add-on antenna that physically mounts to your 310? ... or does the 310 require a special coupling technique (non-connector)?

Yeah, I just wanted to put some "overkill perspective" on his 5-watter.
Some folks equate RF power with an equivalent light bulb and it's just
not a good comparison.

I regularly work to near the horizon on a watt or two (VHF). The QRP
record I've heard is 1/40 W from North America to Australia (CW).

Let him go... the scenario probably goes like this:

He runs 5W out on the farm, it can be heard in town, someone passes
the word around about the cool music on pirate radio, the operators of
the commercial stations hear about it and feel agrieved (loss of
audience, ratings, revenue), the regulator is called in.

Breaches of Radiocommunications Act and Copyright Act to name just a
couple.

All,

I have been experimenting with various loaded antennas to use in my relatively limited space. For this I assumed the two arms of a dipole must be identical to support resonance, this assumption has not been supported by modeling.

Actual model runs show that if the two arms of a dipole are close then there is sufficient interaction that they will combine to form a single resonance. The model below shows a simple example of this. The loads and length of the arms are not equal, however nec predicts a single resonance at about 3.5 MHz. Changes of 10 to 20 percent around resonance seem to create one resonance.

Is there an explanation for this?

Thanks - Dan kb0qil

```
CM 75 m loaded dipole
CM copper conductivity
CE
GW 1 31 4 0 8 0 0 8 .001

An electrical 1/2 wavelength conductor is resonant
no matter where you feed it. Even if you don't feed
it anywhere, it is still resonant.

No matter what Dan, you should see only one resonance at the overall length
of a half wave. Not that resonance has any bearing on antenna efficiency.

Also; your NEC model has uneven segmentation, which does produce significant
errors. Interesting to note that your antenna is also resonant at 7 MHz.

73,

Frank

Dot wrote:
"Low impedance resonances occur every odd multiple (1,3,5, etc.) of a quarter wavelength."

As I read from Arnold B. Bailey, he takes the opposite view. I think a 1/4-wavelength folded dipole shares some characteristics with a short-circuited 1/4-wavelength stub; short on one end, high impedance on the other end. Therefore, I agree with Bailey.

Arnold B. Bailey shows interest in folded dipoles in "TV ans Other Receiving Antennas", He catalogs the first through the eighth resonances on page 410. The odd order (1,3,5, etc.) resonances present high drivepoint impedances. Even order resonances present low drivepoint impedances.

Page 509 is Bailey`s catalog page for the 1/4-wave folded dipole. With a 1/4-in dia rod spaced at 1 inch between sides at 200 MHz, the antenna has a 6000-ohm drivepoint. Cecil says this is too good to be true because a 1/4-wave-matching-section of 600-ohm line would match the 1/4-wave dipole to 50 ohms.

Page 510 is Bailey`s catalog page for the 1/2-wave folded dipole. It has 0 dBd gain and its pattern is the same as a straight dipole. Same as the 1/4-wave folded dipole too for practical purposes.

The 1/4-wave folded dipole has only a 1/2 dB less gain than the 1/2-wave folded dipole, but its resonance is sharper. It has only 5% bandwidth versus 45% for the 1/2-wave folded dipole. This can be an advantage if it prevents receiver overload when using the 1/4-wave folded dipole.

Best regards, Richard Harrison, KB5WZI

> N9NEO
>
Those VHF 75/300 ohms transformers where designed for the 48 to 300 MHz VHF TV-segment. The neosid core is not that small: it just covers my thumbnail. It indeed can handle 100 watts on 14 MHz. I tested it thoroughly: a friend had taken his transceiver to Costa Rica where he was visiting family and I wanted to raise an antenna very quickly to stay in touch with him. I suspended a folded dipole under the roof of my house and used the described VHF bal/un to feed it. We had (almost) daily skeds on 14 MHz. The "almost" was not due to propagation but had more to do with the fact that the electricity plant was only up 3 or 4 days a week in Costa Rica at that time.

Later I used the same bal/un with a folded dipole for the 20 m band made with twin lead.

I never used it on lower frequencies. I am sure that it would get pretty hot with 100 watts on 80 m.

Kind regards,

Phil

"a 1/2 wave segment is resonant no matter where you feed it." That allows for a large single coil to 'tune' one arm of an antenna and for the other to be adjustable.

Simulation predicts the impedance will change when it is not feed at the center, it appears to go up as the feed point is moved.

I will play with the segmentation and see what happens.

Thanks - Dan

Hi Dan,

I don't know where to start on that one. 1/2 wave "segment?" And
then to partition (into what? it is already describe as A segment) for
a feed - that is resonant irrespective of where it is fed? Any wire
is resonant, further elaboration does nothing to change that one
obscure characteristic - and in fact, any wire is multi-resonant.

>That allows for a large single coil to 'tune' one arm of an antenna
>and for the other to be adjustable.

Then it ceases to be "a 1/2 wave segment" unless the frequency is
adjusting with the length - this would seem to be obvious, but what
end is served in saying it? What distinguishes an arm from a segment?

>Simulation predicts the impedance will change when it is not feed at the center,

Simulation should.

> it appears to go up as the feed point is moved.

In distinct contradiction to most OCF dipoles - odd. In fact one of
the hallmarks of the OCF is being resonant in many ham bands where the
standard dipole does not.

Dan,

As for NEC segmentation. "0.05 wavelengths per segment is preferred, but can be as long as 0.1 wavelengths. Segments shorter than 0.001 wavelengths should be avoided". From L. B. Cebik's "Basic Antenna Modeling: .....". In most cases all segments within a structure should have equal length segmentation. Where antenna models become very large, with 1000 segments or more, there are work-arounds which allow for uneven segmentation without introducing errors. The problem with large numbers of segments is that processor time increases dramatically.

I see nothing wrong with using one loading coil in a dipole. The effect is simply the same as an off-center-fed dipole.

This winter I have been working on the design and construction of a compact loop for 80 meters. The loop will be constructed from 72 ft of 3/4 in copper pipe and will be in the shape of an octagon. The plane of the loop will be vertical, and the loop will be remotely tuned by a vacuum variable capacitor coupled to a geared stepper motor.

I have just finished constructing and testing the driver for the stepper motor. See
http://tinyurl.com/bwobb for pictures and some information about the system. Constructive comments will be appreciated.

==========

Just go out into the garden and look up at the antenna.

If each half of the doublet is of about the same length, and both
halves are about the same height above ground, then the parallel pair
of wires are balanced.

Resonance has NOTHING to do with impedance. Resonance is resonance; it has a harmonic response.

Feed point impedance is the load presented to a transmission line when you want to make a wire, any wire, resonant or non resonant, into an antenna. I can feed any antenna with a single wire against ground, I can feed the same antenna with 50 ohm coax, 70 ohm coax, 90 ohm coax, 72 ohm balance line, 300 ohm balanced line 450 ohm balanced line 600 ohm balanced line. None of these transmission lines changes to resonance or non resonance of the antenna.

Resonance is determined by the physical characteristics of the antenna. Generally these include the antenna length and the length to diameter ratio. PERIOD.

Balance requires that the currents in the two wires be equal in magnitude and opposite in phase (or direction). How do you connect an RF ammeter to determine this?

Hi Amos,

Resonance is the absence of reactance, or more properly its term is 0.
As reactance is fully part of the specification to impedance,
resonance has a very unique relation: r ï¿½j0.

You can take a dipole that exhibits this unique characteristic at
regular intervals of frequency - notably at harmonics (in a perfect
world, not so necessarily in life). You can also take that same
length of wire and shift the feedpoint such that its resonance (still
that same characteristic loss of X with some remaining R) changes in
frequency - as does the spectrum of other resonances which are
sometimes no longer related by harmonics.

Taking as an example, an 11 segment 3mm wire 37.9M long in free space
and feed it in the conventional way (in the middle) and its resonances
may be observed at:
3.8 MHzï¿½
7.95 MHzï¿½
11.75 MHzï¿½
16.25 MHzï¿½
19.65 MHzï¿½
24.65 MHzï¿½
27.55 MHzï¿½

Or feed it at 68% along its length (or segment 8) and observe:
3.8 MHzï¿½ (with a Higher R as I had incorrectly argued with Dan)
5.65 MHzï¿½
7.85 MHzï¿½
12.45 MHzï¿½
15.65 MHzï¿½
17.55 MHzï¿½
19.65 MHzï¿½
25.55 MHzï¿½
27.55 MHzï¿½

where strictly speaking MHzï¿½ is resonance and MHzï¿½ is anti-resonance

A curious property has emerged, we now have 9 resonances (speaking
largely) where formerly we had 7 in exactly the same span of frequency
for the same piece of wire. Further, we also have the anti-resonance

of the standard dipole at 8 MHz replaced by a resonance in the OCF dipole.

To roll back the calendar 10 years or so, this is also the hallmark of fractal antennas in that they exhibit more resonances than found in "conventional" dipoles.

There are certain lengths of wire, with certain offsets of feed that offer fairly good overlaps with Ham Bands that are not otherwise found in common dipoles. I am at a loss to specify those "certain" characteristics, and it is arguable that feeding an offset dipole can be successfully achieved without some effort in isolating (choking) the feedpoint from the driveline - a distasteful reality conveniently discarded in modeling.

On a standing wave antenna, like a center-fed dipole, the feedpoint impedance is (Vfor+Vref)/(Ifor+Iref) where Vfor is forward voltage, Vref is reflected voltage, etc. and the plus sign denotes superposition, i.e. phasor addition.

On a wire dipole, the resonant feedpoint impedance will occur only when all the phases line up, i.e. If Vfor is at zero degrees, Vref must be at 180 degrees, Ifor must be at zero degrees, and Iref must be at zero degrees. That way, we get minimum voltage divided by maximum current with a resultant phase angle of zero degrees. Eureka! The dipole is resonant because the feedpoint impedance is purely resistive.

The easiest way is to use a large sampling toroid such
that the balanced line can be fed through the toroid.
A ten-turn sampling coil will indicate any unbalance.
Note that the balanced line needs to be centered with
respect to the toroid and needs to be moved along the
feedline to obtain maximum accuracy. Ideally, the toroid
needs to be located at a standing wave current maximum
point. Since my choke-balun is always located at a current
maximum point, I can easily monitor my feedline balance.

You can also use smaller toroids on each line and then
superpose the two readings. But the two toroids need to
be identical which is no small requirement.

Cecil, are you saying that a resonant dipole must have a low
impedance, and that modes where the feedpoint impedance is purely
resistive but high are not "resonant"? That seems to be what your
formulae above and explanation suggests.

Yes Owen, that's what I am saying. When I was at Texas A&M in
the dark ages, we called the feedpoint impedance of a one-
wavelength dipole an "anti-resonant" impedance. It is explained
at: http://dx.doi.org/10.1036/1097-8542.041800
"Antiresonance - The condition for which the impedance of a
given electric ... system is very high, approaching infinity."

Semantics strikes again. To distinguish the left-most low resistance
point on an SWR circle from the right-most high resistance point, we
mid-20th-century Aggie EEs called the leftmost point, "resonant", and
called the rightmost point, "anti-resonant".

If you and I were ever to agree on definitions, I have no doubt
that we would also agree on concepts.

I am sure we are talking the meaning of the terms (semantics) rather than the underlying concept.

Narrowing the term resonance to only apply to the resonance that exhibits a series resonance equivalent behaviour seems to me to unnecessarily limit the meaning of resonance (though I note it is used in optics to some extent).

I think of the high impedance of a dipole with zero reactance at some frequencies also as a resonance, and I think you did too when you said recently to Amos "jX is only zero at resonance." If that is to mean that jX is "only ever" zero at resonance, then if jX is zero, you have resonance, whether R is high or low.

On that basis, one would have to say that a full wave centre fed dipole exhibits (at the feed point) resonance similar to a lossy parallel tuned circuit and should be considered a resonant radiator.

Resonance has everything to do with impedance. Resonance is defined as any frequency at which the impedance is purely resistive; that is, where the reactive part of the impedance is zero. And that is all resonance is.

You can change the resonant frequency of an antenna by simply adding a series or parallel inductor or capacitor at the feedpoint. This doesn't change the antenna characteristics in any other way than to alter the feedpoint impedance.

Initially, at least, the loop will be just high enough so that a lawnmower can get underneath the lowest side of the octagon. It the loop works fairly well, I might install a 40 foot fiberglass flagpole and suspend the top of the loop from the top of the flagpole. Supposedly, that might cut down on some loss due to ground currents.

John, just for interest I placed the top of the antenna at 30 ft; which puts the base at about 8' 3". Using NEC's Sommerfeld/Norton ground with: sigma = 5 mS/m, and Er = 13. The input impedance computes to 6.57 + j855.6 ohms. Since this is very close to the edge of the Smith Chart, your 1 ohm figure is probably within a reasonable margin of error. However I cannot see how you can match such an impedance with a single element.

The structure appears to be a very efficient, physically small, antenna. NEC computes 0.84% copper loss.

An unbalanced condition would have a meter indication, like current
flow? Balanced the meter needle would not move? I want to monitor this
condition on the feedline in the shack from the Johnson KW matchbox.

I plan to feed the loop at the side opposite to the side containing the tuning capacitor. Note that the capacitor is inserted in series with the loop and is used to tune the loop to resonance at the operating frequency. A gamma match is used to connect the coax to the loop, and the loop is NOT cut on the feed side.

I know that is what your gut feeling wishes were true. But a
large portion of the RF engineering community considers "anti-
resonance" to be the exact opposite of "resonance" and indeed
it is the exact opposite on a Smith Chart, being the opposite
side of the SWR circle. Semantics strikes again. I'm sure that
our Russian counterparts have a completely different word for
exactly the same effects.

In the distant past, when I had a dinosaur for a pet, resonance
was defined as the frequency at which the impedance is a purely
low impedance. The frequency at which the impedance was a
purely high resistance was known at the anti-resonant point,
the exact opposite of resonance, and indeed, it was the exact
other side of the SWR circle on a Smith Chart.

Hi Roy,

I have a couple of RF current meters with freq. response from 10KHz to 100MHZ that are the types used for FCC part 15, DO-160E testing etc. and have a transfer impedance of 0dB-ohm. They have an opening of about 1.6" dia. and I sqeeze the feedline together (spacing about 1.5") temporarily and clamp over both conductors for measurement #1 and clamp over just 1 of the conductors for measurement #2. I read the output of the current probe with an RF power meter. In my case the current in a single conductor was approximately 15dB above the differential current which seemed to be pretty well balanced. Is there anything wrong with this approach?

Egad. Calling it antiresonance is asking for (communications) trouble, since not eveyone uses the same terms. Just call it "half-wave resonance" and "full-wave resonance". I don't think I've EVER heard anyone call a parallel-tuned circuit "anti-resonant." I do regularly hear people distinguish between series and parallel resonance, however. I'm not likely to soon adopt "antiresonance" for either condition, as it sounds way too much like something opposing resonance.

Cheers,
Tom

Not that I can see. In my opinion it's the best way to make the measurement. A homebrew version of this is entirely adequate, though, as described in the earlier thread. It's very important to terminate the secondary with a fairly low impedance so the transformer doesn't present a significant impedance to the line. I assume your meter does this internally -- maybe that information is in the transfer impedance you mentioned and which I don't really understand.

In a transmission line with reflections, antiresonance is
indeed plus or minus 90 degrees from resonance and "never
the twain shall meet". Resonance and antiresonance cannot,
by definition, occur at the same point, i.e. if a point
is antiresonant, it cannot, by definition, be resonant.

Quoting "Transmission Lines and Networks", by Walter C.
Johnson, PhD. (one of the heavyweight gurus of the mid-20th-
century) page 156: "When the lossless line is an odd number
of quarter wavelengths long, the sending-end impedance is
theoretically infinite (inversion of the receiving-end
impedance). The actual impedance, considering losses, is a
very large resistance, and the line is said to be ANTIRESONANT."
(Capitals substituted for italics for obvious reasons)

So your argument is with Walter C. Johnson, PhD, ex-chairman of
the Department of Electrical Engineering at Princeton University,
not with me.

True, but I cannot take credit for the definition which comes from
"Transmission Lines and Networks", by Walter C. Johnson, PhD, guru
and chairman of the Department of Electrical Engineering, Princeton
University during the 1940's and 1950's.

Roy,

It is amazing how a simple concept such as impedance can be made obscure but most current probes are spec'd this way by the manufacturers and test procedures for DO-160E (FAA aircraft testing) call out probes the same way. By saying that a current probe has a transfer impedance of 0dB-ohm means 0dB relative to 1 ohm, but R = V/I so 0dB-ohm means that for 1A of current thru the primary of the probe produces 1V across a 50 ohm load. Similarly a -20db-ohm transfer means that 1A produces .1V across a 50 ohm load. For most of us, this means a 1 turn primary and a 50 turn secondary which yields a theoretical primary impedance or 0.02 ohms. One of the probes I have says the primary impedance is less than .1 ohm.

You will know that also with a transmatch!!!!

I've used a transmatch for almost 45 years out of 50+ years in Ham Radio. If my antenna has a problem the settings for a 'match' [in quotes] change!! That indicates something has happened.

The system SWR increase can be seen in the changes transmatch settings.

One more thought: In a transmission line with reflections,
a voltage node is located at a point of resonance. A voltage
anti-node is located at a point of anti-resonance. Makes
perfect sense to me.

Not at all. As you can see at: http://www.qsl.net/w5dxp/notuner.htm,
I use "the feed" for the specific purpose of changing the resonant
frequency of the antenna system. The impedance transforming series-
section is really a series stub which resonants the entire antenna
system.

Hi Amos,

Where do you see that in the data? Or are you mis-interpreting the distinction between the choice of the feed point with attaching a feed line? The model distinctly lacks a feed line, or may be presumed to have a feed line that is completely isolated from the antenna(s).

The wire retains its original fundamental resonance - within a couple dozen KHz, a negligible difference. The remainder of its resonances are strictly governed by the selection of the feed point's position along the length of the wire. I incorrectly argued for a lower Z with Dan earlier. By and large, moving away from the center raises the Z (principally R at resonances above the fundamental).

The two points are exactly the same.

The high-impedance full-wave resonant point (for a dipole; half-wave
resonant point for a monopole) is sometimes called "anti-resonance", but
not commonly, and mostly in older literature. It's a true point of
resonance, that is, where the reactance is zero. I don't believe I've
ever heard the term "anti-resonance" applied to other high-impedance
resonant circuits, such as a tank circuit.

> It would then be reasonable for a given wire perpendicular to a good ground

> started out in this discussion....

If you choose to call the high-impedance resonant points
"anti-resonance", that's true. But again, they're points where the
reactance is zero, just like the points you're calling "resonant". The
only difference is that the impedance is high and the antenna acts more
like a parallel tuned circuit at nearby frequencies rather than a series
tuned circuit.

> Your semantics is correct if you are looking to define an antenna as "a
> current fed device", but that's not always the case. There are end fed half
> waves out there... they are voltage fed, they are resonant and they do work.
> (Ask anyone who owns a "Ringo Ranger".)

No, the definition of resonance has nothing to do with how an antenna is fed. The impedance of the antenna doesn't change with the feed method (assuming of course that it has a single feed point), and therefore its resonant frequencies don't change with the feed method. (You can, of course, alter the resonant frequencies of an antenna *system* by adding reactance at the feedpoint or elsewhere.) And an antenna doesn't have to be resonant (that is, have a non-reactive feedpoint impedance) to "work". Resonance is only an indication of the reactance of the input impedance, and has nothing to do with an antenna's gain, pattern, bandwidth, or other performance characteristics.

Thanks for the explanation. My concern is with the insertion impedance, which at 0.02 or even 0.1 ohm, is certainly adequately low for this device -- as long as it's properly terminated.

That's why these probes which are about the size of a small donut cost over $1000. Since they are used to qualify EMI emissions from other equipment they are priced like test equipment and certified to be accurate. Generally the frequency response if terminated properly is flat to within a fraction of a dB. Occasionally they show up on eBay and usually go for less than $100. With no parts to wear out they never go bad unless they have been used to test equipment for EMI susceptability where you transmit RF into them, sometimes at high power levels.

Hi Dan, this is essentially the initial code that I used. I have just removed, and replaced, the "GM" card by a series of "GW" cards.

Note that John mentioned he is using a gamma match, and tunes out the reactance of the loop on the opposite side. The diameter of the loop is a nominal 20 ft, so it would make the most sense to tune, and feed, the antenna on the two vertical elements. My model is 30 ft at the top, and 8.272 ft at the bottom, so even with the reduced height motorized tuning makes a lot of sense. I am going to model a gamma match, and opposite side tuning cap, so will update the code this weekend.

The antenna is virtually lossless, with a 99.8% efficiency, and even exhibits quite a good low angle performance. The gain at 25 deg elevation is 0 dBi. I have no experience with gamma matches, but if you can build a practical model with 3/4" pipe, then I would guess its loss would be low. Also note the input voltage is 27 kV with a kW input.

73,

Frank

Source record: 64087

If you have a Ground Mounted, or an Above Ground Mounted vertical, can
you create a lobe by placing your radials pointed in the direction you
want the lobe to occure? or, does the lobe occure in the opposite
direction from which you have the radials pointed?

What is the optimum length for radials:

1/10 wavelength?

1/4 wavelength?

1/4 wavelength plus 2%?

1/2 wavelength?

1 wavelength?

2 wavelengths?

Is the optimum wavelength a function of where the vertical is mounted?
i.e. Ground Mounted or Above Grounded Mounted.

Thanks for your help.

PS, inserting a 50 pF capacitor on the opposite side to the feed point -- as John mentions on his web site -- makes the free space input impedance 1.1 ohms. 30 ft, at the top, above an average Sommerfeld/Norton ground, the input impedance rises to 2 ohms.

One feed method is center feed. Another feed method is off-center feed.
The feedpoint impedance of the antenna changes with position since
for 1/2WL, for instance, the net voltage is a sine wave referenced
to the center, and the net current is a cosine wave referenced to the
center. The feedpoint impedance is approximately sin(x)/cos(x)=tan(x)
where 'x' is the number of degrees away from center.

I think the cheapest and best performing antenna you could make is a 300ohm twinlead J pole. There are several websites though I would be willing to send you the pdf from QST if you like. Cost is <$10 and <20min to construct. Can mount it on a stick or in a pvc pipe. Performs better than a dipole and is fed directly with coax with low SWR. At 5 watts, though, coverage could hit a hundred square miles depending on the topography. Maybe 100mW would be better, huh?

My external antennas are all non-specific to the brand and model of consumer-grade GPS receivers (those using only the L1 signal). The connection method varies among receivers.

If you are buying an antenna, here is Garmin's web link to the manual: http://www.garmin.com/manuals/StreetPilotc310_OwnersManual.pdf

See page 26 for a mention of the GA27C antenna. Of course, it comes with the cable end being the right connector (MCX) for your receiver. Hunt in your manual if the pages don't match the one I found online.

If you are making your own antenna from plans I linked to, you will need to also buy a type MCX connector for the cable end, as that is the connector type specified here: http://www.garmin.com/products/sp330/spec.html (which is the link from page 26 in the manual.)

www.jameco.com sells MCX connectors, but if you google for "MCX connector" (with the quotes) you will get not only sources for the connector but also quite
a few third-party vendors with ready-built GPS antennas using that connector.
You are apparently in a large group of Garmin users who want an external antenna.

They also come in larger sizes than donuts. A friend who works in
radiation protection uses them to measure RF currents in the wrists and
ankles of workers, eg operators of machines for RF welding of plastics.

But all these things have to be tested first... which is how he found
himself with one of these big toroids clamped around his ankle,
standing outdoors on the chicken-wire groundplane of an HF monopole, in
bare feet, in November. All in the name of "Occupational Health"... but
definitely not his own.

Testing has shown no discernable difference in a vertical pattern when
certain directions are favored with the radial system.
So many hams feel they get best performance from end fed halfwaves
with 4-7 "counterpoise rod", and are only fooling themselves. A 1/4w
vertical with 60 on gorund radials is a very
efficient antenna on long hauls.
Good luck,
Jim

Most people put the series tuning capacitor in the top side and the feed point at the bottom side. Since the capacitor, motor, and their mounting hardware is quite heavy, I am currently planning to do the reverse of the above, i.e., tuning capacitor at bottom and feed point at the top. It is not clear to me if there is any difference between these two configurations.

I have not attempted to model the gamma match, but doubt it will change the current distribution. Feeding at the top places the minimum current at the loop base which seems to effect the high angle radiation only. The gain straight up is about + 2 dBi, and -3 dBi when reversed. Low angle radiation, for example at 10 deg elevation, is - 3 dBi in both cases. Removing the capacitor totally reverses the current distribution. Maximum gain occurs parallel to the loop plane.

Also top feed increases the input impedance to 2.664 - j0.949, with the
capacitive load 0.1 -j858 at 3.75 MHz. (NEC 4.1 double precision).

Actually I want to monitor the antenna because I have a splice in the
feedline and the feedpoint is subject to wx, snow ice and rain. Some
times the feedline itself is covered with snow and ice. I would find it
interesting to see what is happening when I see my SWR shoot up and
retuning my matchbox. I also have a strange thing happen when I apply
high power, I get a slight bump up in SWR suddenly. I often wonder if
one of my end insulators are breaking down under 1KW of RF or if there
is some imbalance on one leg due to ground or trees swaying in the wind.

1745. 50 Or 75 Ohm Coax For Receive Only Application ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-25 18:24:39 UTC
From: Robert11 <rgsros@notme.com>

Source record: 64106

Hello:

Will be putting up a new HF atnenna for Receive-Only, to be used from 30 MHz on down

Trying to decide on a coax type for the radio to antenna run, about 150 feet.

As some will be buried in soil, want to have a PE jacket.

It appears that when factoring in the PE requirement, and certainly price, I can
do better, apparently, by picking a 75 ohm coax than a 50 ohm one.

My receivers input is, of course, stamped 50 ohm.

In a practical sense, do you experts believe I would see any difference between
50 or 75 ohm coax for a receive only situation at the 30 MHz and lower listening freq's (150 foot coax run) ?

Thanks,
Bob

For receiving it will not make any differance. Even for transmitting it
will only mater if youare using a 50 ohm swr or power meter and want to read
it directly. Just use almost anyting but rg-58 or rg-59 is fine and those
are not too bad. If you could handle the connection of the noncopper
shield that most of the cable TV 70 ohm rg-6 has, that would probably be
your best bet. Don't even go to the real high grade of the quad shielded
stuff.

While the receiver says 50 ohms, it is doubtful that it is actually 50 ohms
except on a very few frequencies if even then.

Hi OM,

Reggie is particularly obtuse to this matter. Simple observation of a dipole that is symmetrical to earth does not guarantee balance. When that twin lead arrives at your gear, you can easily wipe that out (the presumed balance) through an inappropriate connection to ground (through any number of paths that are commonly overlooked in the shack).

Snow and ice on the line are not likely to impart a common mode current, but as revealed by bench test by contributors here, the characteristic Z of the line can change drastically, which then upsets the tune, where it follows SWR begins to change - noticeably. If your feedline is coaxial, then the ice is of no consequence, but that does not remove the jeopardy of common mode current. There you need to look at how you isolate the line from the drivepoint.

I use a lot of 75 ohm coax that I get for free from scrap
ends from the local cable TV company. Can't beat that price.

Source record: 64110

Cecil, read your post closely. then Read my post.

Antenna and antenna system are two different [read different] things.

A physical length of wire of dimension 'L' is 1/2 wave resonant at it's fundamental frequency, 3/2 waves resonant, 5/2 waves resonant, 7/2 waves resonant, at harmonics of the fundamental etc.

An antenna system is what connects the antenna to your radio in a manner where your radio can deliver energy efficiently to the antenna. it includes feedline, stubs, tuners, etc. these things are not part of the antenna but are part of the antenna system.

Once again, the basic resonance of a wire is the basic resonance of the wire. You can fiddle all you want with stubs, tuners, or what not, and still not change the resonance of the wire.

A 100 feet long wire is 1/2 wave resonant at 4.68 MHz [depending on which formula you choose]. You can tune it to transmit where you want. But the wire is still resonant at 4.68 MHz while the antenna system may be tuned anywhere between dc and light [hyperbole].

AK

==========
I quite agree.

Of course, if there's anything the matter with the antenna then you will be aware of it long before you discover whether or not there's any need to get out your measuring instruments to find how much your feedline is unbalanced.

Just go out into your back yard and see whether your antenna is still up in the air or not.

Many years back I once had a neighbor who sabataged my inverted-L at 1am in the morning while I was on the air. I did NOT measure unbalance on the feedline - I was not equipped to do it - I just called the police!

It turned out that my neighbor had very sensitive ears and could hear my microphone voice through the walls of our adjoining houses.

A lot of questions in one post...
You can get some of these answers by downloading the demo package of
EZNEC. I dropped a radial from one of my test cases and found the
pattern was less on that side of the azimuth display.

Modeling buried radials is beyond my talents.
In general, more is better and longer is better. The jury is still out
in most cases.

Most of your questions are addressed in the 20th Edition Arrl Antenna
Handbook.

You can use Google to search in the Groups and also find answers to
most of your questions but that is the least reliable source that I
use. Beware of experts who use assumed names, especially!

Consider any advice from me as coming from a student in spite of old
call and the Social Security Check!

1754. 75 And 50 Ohm Connectors In Same Listening Chain ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-25 20:32:06 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <_rOdndQpXOwhI53ZnZ2dnUVZ_sGdnZ2d@comcast.com>
Source record: 64115

Hello,

Should have asked this also in my previous post re 50 or 75 ohm coax, but
I guess it is probably better to start a different thread.
New at this, so please pardon these very basic type of questions.

For a receiving only application, 30 MHz on down:
Putting up a new Inverted-L receiving antenna.

Radio, Balun, Lightning Arrestor use the 259 type of plug which I guess is
nominally for 50 ohm systems.

I can go with 75 ohm BNC connectors for the main coax run, but am pretty
well stuck with the
259 type for the already purchased units I noted above.

Intuitively, I guess I would like (all) 75 ohm connectors if I am using 75
ohm coax.

But, for 30 MHz and lower listening, would I even notice any difference,
probably ?

Is any received signal lost, or reflected back, at these 75-50 ohm junctions
?
If meaningful, any way around the problem ?

Thanks,
Bob

I may have inferred from Roy's posting what he didn't mean
to imply. Here's what I assumed he said: "The *feedpoint*
impedance of the antenna doesn't change with the feed
method." I hope you agree that is a false statement but
may not be the meaning that Roy intended. I apparently
made the same mistake for the meaning of your posting.
If you guys would just post in Texan, I could understand
you. di-di-di-dit---di-dit

If Roy had said, "The radiation resistance of an antenna
doesn't change with the feed method", I wouldn't have
questioned it.

There is no such thing as an 'optimum' length of radials.

There is only an economic limit to what your bank balance can afford
in terms of number of dollars per S-point.

Most people's bank balance and lumbago problems run out when there are
half a dozen radials of about 15 feet in length.

Source record: 64119

If you MUST use coax then prefer 75 ohms. Go for the greatest overall
75-ohm coaxial diameters. The greater the overall diameter the smaller
the attenuation in terms of dB per 100 feet.

There's no need to impedance match a 75ohm line to a 50-ohm receiver
for receiving purposes. The mismatch loss is quite small.

What matters is a severe mismatch between the antenna impedance and
the line impedance which will occur on some of the higher frequency
bands.

In this part of the world, some types of quad shield, and even some
types of the dual sheild have one of the braids made from tinned
copper and are solderable, check out the specs or get a sample and
test it.

Additionally, crimp BNC(M) connectors, F(M) connectors and F(F)-BNC(M)
adapters are available.

Firstly:

Some types of connectors are designed to create a minimal
characteristic impedance discontinuity, examples are N type and BNC.
PL-259s are not so designed.

Secondly, at HF, the impedance discontinuity of PL-259 or 50 ohm BNC
in a nominally 75 ohm line for your intended use is insignificant.

Beware of having 50 and 75 ohm versions of BNC and like around,
incorrect pairing risk damage to the female connector. Most 75 ohms
applications still use 50 ohm BNC connectors, even though 75 ohm
versions are available.

Owen

Yes, we can readily calculate the effect of introducing a
discontinuity, the effect is so small in your application that you are
unlikely to be able to measure it, much less see the effect in
receiver signal strength.

Simply forget about that worry. PL-259s are not 50 ohms.
That's why they are not used at VHF/UHF.

I apologize for not being more clear. The context of my comment was in reply to a statement about the resonance somehow being different for "current fed" and "voltage fed" antennas. What I meant was that the antenna impedance is independent of the source impedance or other characteristics of the source. Of course, the feedpoint impedance will be different if you choose another feedpoint.

I'm surprised that this topic has aroused so much commentary. It reveals a general lack of understanding about some of the most basic and fundamental characteristics of antennas and circuits in general. Hopefully, the discussion is helping some of the readers to gain a better grasp of the subject matter.

Times certainly have changed. I remember as a NOVICE being drilled that a coax fed 1/2 wave dipole will not work on EVEN multiples of the fundamental. Maybe I needed a ANTENNA TUNER, whatever that is.

Not being critical OM, I applaud you for trying to learn instead of spouting garbage from CB. Keep up the good work.

A center-fed dipole has a "single feed point". An off-center-fed
dipole has a "single feed point". The feedpoint impedance of the
antenna does indeed change depending upon where that single
feed point is located.

I recently finished reading Richard Hofstadter's _Anti-Intellectualism in American Life_ (written in 1962, won a Pulitzer prize in 1964), where the author shows in great detail that a general disdain for education, sophistication, and complexity is a very deeply seated American tradition. That general outlook was virtually a basis of the founding of a number of now-mainstream religions, and has had lasting impacts on our educational and political systems. In short, it's a long and dearly held American tradition.

So, Reg, that was a very American thing to say. You'd fit right in here.

I recently came across some other notable quotes from Lord Kelvin:

"Radio has no future."
"Heavier than air flying machines are impossible."
"X-rays will prove to be a hoax."

-- quoted in _Unweaving the Rainbow: Science, Delusion, and the Appetite for Wonder_, by noted British writer Richard Dawkins. Dawkins also notes that "William Thompson, first Lord Kelvin, was one of the most distinguished and influential of nineteenth-century British physicists. He was a thorn in Darwin's side because he 'proved', with massive authority but, as we now know, even more massive error, that the earth was too young for evolution to have occurred."

The value of Kelvin's contributions is unquestionable. But even he didn't get it right all the time.

I'd recommend a good grade RG-6 cable (70ohms) also. Regarding the connectors, why not just use the standard TV F fittings all the way to the Rx. You can put an F to whatever adapter on your Rx. TV cable and fittings are not only cheap, but work quite well.

The topic of radiation resistance has been pretty much beaten to death on this newsgroup. A groups.google.com search should provide a good evening's reading and entertainment.

In brief, "radiation resistance" is the part of an antenna's impedance which "absorbs" the power actually being radiated. It can be referred to any point on an antenna. At that point, wherever it is, the power radiated is I^2 * Rrad, where I is the current at that point. Kraus generally refers the radiation resistance to the feedpoint; that is, he calls the resistive part of the feedpoint impedance the radiation resistance. In AM broadcasting, where monopoles are often higher than a quarter wavelength, it's common to refer the radiation resistance to a point of maximum current. Either approach is perfectly valid. But it means that you have to be careful to say what you mean when you use the term, particularly if the antenna is longer than a quarter wavelength (monopole) or half wavelength (dipole).

There's a common equation for efficiency, Eff = Rrad / (Rrad + Rloss). When using it, you have to make sure you're referring Rrad and Rloss to the same point. A common error when dealing with folded monopoles is to refer the radiation resistance to the high-impedance, transformed feedpoint, while neglecting to refer the loss resistance to the same point by transforming it. This leads to the erroneous conclusion that folding the element improves efficiency. It doesn't, except that the additional wire surface area reduces the wire loss -- but this isn't usually a significant contribution to the total loss.

So to address the comment --

Changing the feedpoint location can change the current distribution on the antenna. This in turn will change the radiation resistance referred to some fixed point along the antenna, although in most common cases I can think of, it won't be a large change. You could contrive some cases where it would. If you refer the radiation resistance to the feedpoint, that is, define it as being the resistive part of the feedpoint impedance, then changing the feedpoint location can have a major impact on the radiation resistance.

Again, if you want more about the topic, read some of the threads where it's been discussed in more detail.

No. You wouldn't even if you were transmitting.

> ?

No significant amount. The length of the discontinuity is extremely short compared to a wavelength, and it's not a terribly bad discontinuity. You'd be hard pressed to measure the difference at HF, even with very good equipment. (Of course, you could see it with a high speed TDR, but that's not an HF measurement.)

I keep reading this, and it puzzles me. I have a number of RG-59 patch cables which have 75 ohm BNC connectors fitted (and others with 50 ohm connectors). As far as I can tell with a magnified inspection, the center conductor of the 75 ohm male BNC is the same diameter as it is in a standard 50 ohm BNC. The only apparent difference is that the dielectric around the inside of the outer mating area is much thinner in the 75 ohm connector, and the diameter of the 50 ohm center pin steps up as it enters the solid dielectric at the bottom while the 75 ohm center pin doesn't.

If some 75 ohm BNC connectors have a smaller center pin, then it looks to me like you can't even safely mate a male 75 ohm BNC (of the type I have) with a female 75 ohm BNC (which might be of this other type if it exists).

Does anyone have a drawing or measurements showing that 50 and 75 ohm BNC connectors really have different pin diameters?

I don't know about type N connectors -- I don't think I've ever seen a 75 ohm version.

>fittings are not only cheap, but work quite well.

Agreed Ed.

I did see another post that suggested 50 ohms was better and to spend
the money.

The matched line loss of 150' of RG6 at 30MHz is 1.6dB. the MLL of
more expensive RG58C/U is 3.6dB, or the much more expensive RG213 is
1.6dB.

The antenna will not be matched over the whole range, so mismatch
losses will occur with both types of line, and there is no reason to
think that overall spending more money on RG213 with the attendent
loss of flexibility will actually be better.

In this rx only application, especially below 15MHz, even if the RG6
was a few dB worse than 50 ohm line, it would not be worth spending
the money on RG213.

Robert, if you want to bury the RG6, buy the standard grade and fit it
inside 13mm PE irrigation tube for better life.

Hi Al,

Too much worry can come from too little problem. You need only ask
yourself does the line inappropriately inject receive signal from the
nulls of your antenna; or do you get RF in the shack? If neither are
a concern, there is certainly nothing worse to worry about.

>I keep reading this, and it puzzles me. I have a number of RG-59 patch

Roy,

I have clear recollection of 75 ohm BNCs (meaning a BNC connector
desiged for 75 ohm through impedance) that were incompatible in days
when I worked in communications facilities that used 75 ohms for IF
(70MHz) and baseband, and 50 ohms for RF (GHz).

However, I note on Amphenol's site:

"Two distinct types of 75 ? BNC's are available, and both mate with
each other and with 50 ? BNC's. Type 1 is designated 75 ? BNC-T1 and
provides constant 75 ? performance with low VSWR DC ï¿½ 4 GHz. Type 2 is
designated 75 ? BNC-T2 and is usable with low reflection DC - 1 GHz.
For applications above 1 GHz, Type 1 is recommended. "

Though it is clear that Amphenol and probably some other manufacturers
produce compatible connectors, I am mindfull of earlier experience,
though I concede that it may have been the result of non standard 75
ohm BNCs.

If the antenna system can be satisfactorily matched to the transmitter output impedance, it would seem to matter little whether the feed line currents are balanced, or, if they are not, by how much.

If there are no obvious common mode currents causing problems in the shack, then of what consequence would an imbalance be, other than to modify the radiation pattern, perhaps even beneficially?

I used to have a Motorola UHF (450 MHz) ex-taxicab radio. It used UHF (PL-259/SO-239) connectors.

At very high frequencies where the impedance discontinuity might become noticeable, the resulting reactance can usually be compensated for by slight readjustment of matching networks which are usually present anyway.

UHF connectors are poor for a number of mechanical reasons, but the impedance discontinuity is seldom a problem.

I think Owen means, "even if the RG6 was a few dB *lossier*". In receiving applications at HF, added loss (within reason) doesn't translate to any reduction in signal/noise ratio. So one line can be considerably lossier than another without making it even one little bit worse in this application. There's no point in spending extra money on line which won't make any improvement at all on your ability to receive signals. It might, on the other hand, be worthwhile to pay extra for line which will last longer or is more physically rugged. Or it might not.

You have to remember that the common mode feedline current doesn't stop at the rig. It continues to the Earth by whatever means are available. So your house wiring, appliance cords, and other odd conductors often become part of your antenna system. These aren't likely to be very efficient radiators. People often go to a lot of trouble to put their antennas high and in the clear. That doesn't make much sense if you're going to have your house do a good part of the radiating.

But you can still talk to lots of stations even if some of your radiating is being done by your feedline and house wiring. And that's enough for a lot of folks.

I agree with what you say.

But antenna (or line) unbalance and line-to-antenna impedance mismatch
are not entirely independent of each other.

An unbalanced line or antenna causes a small impedance mismatch.
Because it is small is the reason why it very often happens it doesn't
matter very much whether or not a balanced feedline is used.

For example, a coax line can be used quite successfully to feed a
balanced dipole.

And, in practice, no antenna is perfectly balanced about ground.

Quite.

The chart at http://www.vk1od.net/bpl/AreYouReady.htm shows that for a
good HF receiver, the ambient galactic noise is more than 10dB above
the rx noise floor. For an older receiver, the rx noise floor might be
10 to 15dB higher. The ambient noise due to man made and atmospheric
sources would be even higher than the galactic noise plotted in the
chart.

"I don`t think I`ve EVER heard anyone call a parallel-tuned circuit antiresonant."

There are many synonyms I am unfamiliar with also, but I`ve heard of antiresonance and used the word. My "Dictionary of Electronics" says:
"Antiresonance - A type of resonance in which a system offers maximum impedance at its resonant frequency."

An antiresonant circuit is defined:
"Antiresonant circuit - A parallel-resonant circuit offering maximum impedance to the series passage of the resonant frequenccy."

A parallel-tuned resonant circuit fits the dictionary definition. It`s a synonym for antiresonant circuit.

The purpose of the antenna is to radiate. The purpose
of the transmission line is to transfer the energy from
the transmitter to the antenna with as little loss as
feasible. How much an antenna system is allowed to
deviate from its purpose is up to the individual. When
I was in high school, I didn't much care about the purpose
of an antenna system and burned a hole in my lip.

1. The 50-ohm rating is nominal. I suspect it's all over the map as you
tune around.

2. The mismatch loss going from 75 to 50 ohm impedance is only about
a dB. So, unless you're doing FM, there's little chance that you could ever
hear 1dB (and you'd only hear it on FM if you were right at the "edge").

I'm always concerned about TVI and telephone I. and that is another
reason I hope to have my feeders balanced, so they radiate minimum RF.
I was using a field strength meter while I had the transmitter going the
other day and working the antenna along some table lamps and the
electrical wire I found the F.S. meter would jump up quite a bit. So
what you say about re-radiating house wiring is surely true.

1797. need help with H antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-26 09:43:07 UTC
From: Jim <jbasi@cfw.com>
Message-ID: <a7d80$4400dc75$d80c3807$22503@NAXS.COM>
Source record: 64125

I need help in building an H type of tracking antenna for use around 166-167 mhz. This is for wildlife tracking. I have a couple of handheld 3 element Yagi's that I built using YagiCad to do the math, and they work well, but they are big and clunky.

There are times when I am willing to sacrifice the good f/b ratio of the yagi for convienience, for instance when working in brushy woods. I have used an H for tracking at 151 mhz, but of course, I can't use that one for 166.

My tracking receiver, a King portable, has a BNC connector, so I can interchange antennas quickly.

Is there a web page or magazine article that can help me design my H, or can someone share their experience?

Thanks
Jim

1798. The DELTA LOOP Antenna calculator is now online !

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-26 11:31:50 UTC

Source record: 64009

Good morning to all,

I am happy to announce you that I have put online the DELTA LOOP Antenna calculator

on the antenna web site.

You just have to give the work frequency between 26 to 30 MHz and the number of

elements that you want and the site calculate automatiquely all dimensions and

spacings.

I invite you to try it at :

http://www.antenna-street.com/delta-loop-1en.php

If you have questions or want to speake about, you could use the dedicated forum :

http://www.antenna-street.com/viewtopic.php?t=16

best regards

Source record: 64010

Thanks for the responses.

Put differently, I guess the purpose of the entire station is to radiate and intercept radiated waves containing information. I was trying to explore the benefits and consequences of preventing transmission line radiation as they relate to this more global purpose.

While it is clear that maintaining balance in the line will prevent radiation from the line, some (maybe all) of the radiation prevented might have contributed to the global purpose of the station. For example, radiation from common-mode currents in a vertical transmission line could produce beneficial low-angle, omnidirectional radiation, as has been pointed out often on the group.

It would seem that for the common-mode transmission line currents the antenna system would look like a top-loaded vertical, ignoring the balanced line currents and their interaction with the horizontal portion of the antenna.

The efficiency of the vertically polarized radiation from the line would depend heavily on the station's RF ground system. But basically we would have (for the common-mode currents) a conventional vertical antenna with all its attendant plusses and minuses.

To the extent the AC grounding conductor in the house presents a lower impedance than the station's RF grounding system, we would expect to see displacement currents in the AC system, just as with an "ordinary" vertical using a poor RF ground.

Coupling to the telephone wires also would seem to be a consequence of a vertical radiator with a poor RF ground, rather than a consequence of transmission line imbalance (which I understand is the cause of the radiation in the first place).

So here is my main question: do we object to the vertical radiation per se (i.e., if we wanted vertically polarized radiation, we would have put up a vertical in the first place), or is radiation from an unbalanced line somehow more insidious in that it causes other problems that "ordinary" verticals do not cause? In other words, why do we really care about imbalance?

Reg has called attention to another of my shortcomings: I have no idea how the common-mode line currents that enter a link in the tuner are seen and "processed" by the tuner. It would seem that the link appears as one plate of a capacitor for those currents.

Thanks again for everyone's patience.

Most HF receivers have plenty of sensitivity and most HF bands that would be of interest (with the possible exception of 10-11m) are noisy enough that a lossy antenna is not a huge problem unless the losses are really large. 10db is quite tolerable in most equipment.

Of course, for transmitting you want as little loss as possible.

> se ...?

Maybe an example would help. I model a dipole until
I am happy with the results predicted by EZNEC. The
take-off-angle is perfect for my schedule to AZ.
EZNEC assumes no feedline radiation. I am sloppy
about putting my dipole in the air and lots of feedline
radiation results which goes off in directions not
predicted by EZNEC. Murphey's Law predicts that the
unknown directions will be bad (entropy never
decreases). Besides, half of my feedline is routed
horizontal under the eaves of my house.

So would you rather deal with the devil you know or
trust the angel that you don't know? Does the angel
that you are trusting really understand entropy?

That's a fair question; but here are a few more:

If you have X amount of time available to fuss around trying to
minimize feedline radiation, might you rather spend that time:
1. Having more or longer QSOs with your AZ friend?
2. Working a little DX?
3. Improving your audio?
4. Watching a movie?
5. Making whoopie with the XYL?
6. Any number of other possibilities?

Disclaimer: Nothing should be inferred from the (more-or-less
random) order of the above list. ;-)

If one follows good engineering practice, it becomes second
nature after awhile and consumes only a negligible amount
of time which is usually more than worth it. If it takes
someone more time to learn about feedline radiation than
they are willing to spend, well then what-the-hell,
ignorance is bliss.

> 1. Having more or longer QSOs with your AZ friend?

We run out of things to talk about as it is.

> 2. Working a little DX?

Most of them don't speak Texan.

> 3. Improving your audio?

I'm already famous for my audio. I do a mean Johnny Cash.
I'm also not bad at Elvis. I'm lead bass in the church
choir. They call me the "largemouth bass".

> 4. Watching a movie?

The last movies that I really enjoyed were "Patton" and
"Alien". Most movies put me to sleep (which is not a bad
thing). If you enjoy homosexual sheephearders - well,
it takes all kinds.

> 5. Making whoopie with the XYL?

Divorced in 1984 - I wish it had been sooner.

> 6. Any number of other possibilities?

I do have a part time teaching job and I like riding
my Harley. I also just spent about three hours getting
my birdhouse ready for the Purple Martins that are
returning from Brazil to nest in East Texas. The fact
that I am posting to this newsgroup at this time means
that I don't have anything interesting or productive
to do. :-)

1806. antenna impedance - calculated 10 - 20 Ohms - measured 36 Ohms??

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-27 03:22:57 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <WJ-dnc6gp48L7Z_Z4p2dnA@comcast.com>
Source record: 64017

All,

This is an attempt to add loaded radials to a loaded vertical. The plan is to make a large efficient loading coil for the radials and offset the variable coil in a 'screwdriver' vertical segment.

The antenna is about 4 meters overall with about an load at about 1.5 meters from the base. The antenna is raised about a meter.

The loaded radials are two 1 inch copper tubes about 1.67 meters long. The radial loading coil is connected from the coax shield to the radial coil.

The feed is 50 Ohm coax, the shield is connected to the loading coil and the center to the base.

4nec2 predicts an impedance of between 10 and 20 ohms depending of the assumed values of R in the impedance loads. The actual antenna measures 36 Ohms at the feed.

The question is: What is the basis of the difference between predicted and measured values?

Below is a representation of the nec code used to simulate the antenna.

Thanks - Dan

```
CM 75 m Vertical 12 ft high
CM base 3 ft up - two radials
CM copper conductivity
CE
GW 1 11 0 0 1 0 0 5 0.025

Interesting Dan, I get the same results as you, using your code. At 3.74 MHz the input z is 16.8 +j133. The antenna is resonant at about 3.55 MHz. With your average ground the gain is about -9 dBi.

The only question I have is how certain are you of the accuracy of your test equipment? Did you use a 1:1 balun at the feed point? You may be getting a large current on the outside of the coax.

Frank

1. Have you decoupled your feedline? If you're not using a feedline,
have you decoupled your measurement device?

2. Have you substituted a lumped impedance of about 16 + j133 ohms for
the antenna and observed what your measurement equipment indicates?

4nec2 does have Sommerfeld/Norton. Incidentally my NEC2 gives 15.7 + j
110.6. The 15.8 + j133 comes from NEC 4.1.

Of course not, Roy. I sure hope what I wrote did not suggest otherwise. But I am trying to learn exactly which properties of an antenna system cause house wiring to be "loaded up."

In particular, I am trying to establish whether a top-loaded vertical with the same wire geometry and RF ground as the open-wire transmission line-fed dipole would be just as likely to cause undesirable coupling to the house wiring. It seems to me that it is. If it is not, I'm trying to understand why not.

In other words, is the problem transmission line unbalance, or simply having a radiator with undesirable proximity to house wiring?

One more way to word the question: if you tie the open-wire lines together at the tuner/transmitter and feed the antenna as a vertical, all of the current in the line will be common-mode. Would that be less likely to cause undesirable coupling than the exact same antenna with transmission line unbalance.

I am not advocating unbalanced transmission lines, verticals, or the pursuit of radiation patterns one knows in advance to be undesirable.

I apologize for my prolix and obtuse approach, but I'm not sure how to pose the question properly. I'll try to work on that.

Thanks again.

As a follow-up, is there a practical way to determine how much current unbalance will cause a one dB reduction in power delivered to the antenna, the "lost power" being that power radiated by the transmission line?

It seems like a rather complex modeling problem.

Thanks!

Roy,

No I have not decoupled the feed from the antenna. I will try that tonight. I have wound a 2:1 balun for testing. (anticipating at least a 25 ohm input impedance)

I have measured the antenna with two different instruments. One is an Autek analyzer at the antenna, the second is with an 8405a at the end of 100+ feed of cable. They both show the same results.

Thanks - Dan

Dan, I notice the Autek analyzer only measures the magnitude of the impedance. With any of these lower cost instruments it is impossible to find any accuracy specifications. The 8405A is an excellent instrument, but assume you calibrated it -- short/open/load -- at the end of the 100 ft cable. This calibration should also be carried out on the antenna side of your isolation transformer when you install it. Curious as to what kind of directional coupler you are using for HF. I remember using a small HP coupler for HF, but cannot remember its model number.

Hi Chuck,

When you tie them together, you have to be referencing that "common"
lead to something. Usually that something is ground. Common Mode
current springs into existence by definition.

Where did ground come into the picture? Usually through the power
supply. The power supply gets it from the mains, and thus you see the
origin of getting RF into the house.

I wrote earlier about how a religious devotion to balancing an
antenna/feed can be easily disturbed when you connect your line to the
rig. The rig has a ground connection even if you didn't drive a
ground rod specifically for it, nor purposely establish a ground path.

Some might think that their tuner isolates their twin line feed from
ground. I seriously doubt that is true. Most tuners I've seen use a
voltage BalUn which design violates that form of isolation, or turns
the core into a heating element, or both. Even link tuners have the
prospects of not having a truly balanced connection. I would say the
prospects are much better, as the designers were working toward that
goal, but it is not always achieved.

The first thing I'd try, then, would be to put a 1:1 balun (common mode choke) at the feedpoint and, when using feedline, a second one about a quarter wave down the line. The balun can be constructed by winding the coax (if you're using RG-58 or smaller) 8 - 10 turns on a type 43 ferrite core. Or you can clamp or thread a few large cores over the coax. You can use the Autek to measure the core impedance -- shoot for 500 - 1000 ohms total -- the angle of the impedance isn't important. Unlike the 2:1 balun, this won't disturb your basic measurement in any way, it'll just reduce any common mode current.

If you still get the same result, then there are only two other possible causes I can think of. One is the modeling of the inductors. I've found that a lumped model of an inductor isn't good if there's any appreciable current change in the real inductor from one end to the other due to its physical length. The solution is to model the inductor as a helix. You'll have to add some extra R to the model, however, if the turns are spaced closer than a couple of wire diameters, since the program doesn't account for proximity effect.

The other possible cause is that there's some source of loss you're not accounting for in your model. The inductors and coupling to nearby lossy objects are the most obvious candidates.

Hm, if the Autek measures only the magnitude of the impedance, how does
Dan know the resistance? The model shows about 133 ohms of reactance,
which is much greater than the resistance.

> If it is not, I'm trying to understand why not.

When you have common mode current, it not only flows on the feedline, but continues to ground via whatever path it can. And this is usually the house wiring. So your antenna now consists of the "antenna", the feedline, and the house wiring. The problem here is current in house wiring due to conduction, not coupling.

If you properly feed a vertical, no RF current is conducted to the house wiring. Either a properly fed vertical or a radiating feedline can induce current in the house wiring by coupling, but the amount will depend on (among other things) proximity of the antenna or feedline to the house. Most of us can put a vertical at least a little distance from the house, but the feedline has to come right in.

> In other words, is the problem transmission line unbalance, or simply
> having a radiator with undesirable proximity to house wiring?

Again, the problems are twofold. One is conducted current, and the other is coupled current due to proximity.

> One more way to word the question: if you tie the open-wire lines
> together at the tuner/transmitter and feed the antenna as a vertical,

You would have exactly the same problems in either case, assuming a worst case of imbalance when feeding the antenna normally (which isn't likely). Whatever current leaves the rig via the connected-together feedline conductors (or via common mode current in a normally fed antenna), an equal amount of current has to leave the rig via its chassis or "ground" connection. In a properly fed vertical, this current ends up in the ground system at the base of the antenna. In the tied-together feed, it'll end up getting to ground however it can, radiating and inducing other currents along the way.

> Chuck, NT3G

Nope. You can't generally say that one part of an antenna is radiating a particular amount of the total power. Each part of the antenna creates a field, and it interacts with the fields from all other parts of the antenna. The total power radiated has to equal the total power input less loss, but that's all you can say for sure. An example will help illustrate the problem. Consider a parasitic element in a Yagi. It has considerable current and contributes a great deal to the overall pattern. Yet the total power input to the Yagi element is zero. With zero power input, it can't, by itself, be radiating any power. What it does is intercept some of the power radiated by the driven element and re-radiates it with a different phase and amplitude. So how would you apportion the power radiated by the driven element and the parasitic element?

You might take a look at the current in the driven element and note that it increases or decreases as you put the parasitic element in place and remove it. But the current can either increase or decrease, depending on the length and spacing of the parasitic element. So has the parasitic element increased or decreased the power radiated by the driven element? There's no answer.

You can look at the change in pattern in some idealized cases by modeling. This can tell you what range of effects you might expect in a real situation.

Here is something strange I discovered this weekend. While using a F.S. meter as a RF sniffer, I was probing along some lamp cords that are plugged into one of those extention outlet strips. I have a split block ferrite core which measures one inch square and a 1/2 inch ID hole. So while monitoring the FS meter I placed the core on the 115 to the house outlet thinking that I will see a decrease in FS reading, much to my surprise just the opposite happened, the FS meter pegged out. Why would adding the core cause the FS reading to increase?

That could well be, although I can't match this photo to a specific electric-fence insulator brand. It resembles some of the "pinlock" insulators which can be used to hold wire, polywire, and polyrope (the latter two being wire- or rope-thick strands of a woven plastic, with very-fine-gauge copper wire woven in among it to provide the current carrying capability).

http://electric-deer-fence.com/electricdeerfences/electricfenceinsulators/woodposts.htm shows one such, about halfway down the page.

Another possibility for retaining ladder line would be the insulators made for "polytape" (sort of like polyrope, but formed into a flat woven tape anywhere from .5" to 2" wide). Polytape clips seem to be designed to "clamp down" on the tape, to keep it from sliding back and forth and cutting the insulator (or the tape itself), and this clamping arrangement might or might not be compatible with any given variety of ladder line... the line's conductors might turn out to be too thick for some types of insulator clip.

The electric-fence insulators seem to be be modestly priced - anywhere form $6 to $8 per bag of 25 - and so experimentation might be worthwhile.

Another variant I see at several vendors' sites is the "Isoline New Generation Line Insulator" (seems to have a manufacturer part number of 653.002). It's a single-piece nail-on insulator for wire or polyrope. Looks as if it'd take a ladder line turned sideways and hold it quite securely.

>Does 4nec2 include the ground losses in the feedpoint impedance?

Ground loss is what I thought of at first... Or like Roy says, maybe
coupling to lossy objects. Just as a given. With two short loaded
radials,
on a short loaded ground plane at 3 ft at the base, you will see a
good bit of ground loss unless you are over some really good ground,
like the beach. Heck...Make that a *lot* of ground loss with the base
at 3 ft. Even two *full length* radials would make for a poor ground,
and
excess ground loss at 3 ft. Even 16 radials would barely be mediocre..

There are at least three possible explanations.

The first is one I've come across many times in doing EMI work, and is probably the most likely. What happens is that you've got two or more radiating sources whose fields cancel or partially cancel at the field strength meter. When you reduce the radiation from one of those sources, the field at the meter increases.

The second can be a bit subtle. Suppose you have a wire near an antenna and that wire is, say, 3/4 wavelength long. Very little current will be induced in this wire because it's far from self-resonance. Now put a choke in the wire 1/4 wavelength from one end. Presto, a lot of induced current in the now-isolated 1/2 wavelength portion. This phenomenon can cause common mode current to increase when you add a common mode choke on the feedline, if the current is being induced in the feedline (as opposed to conducted) and the wire length and choke position are favorable for this to happen.

The third is that the core you're using is a high frequency ferrite. If it is, it will act as a loading coil, which could make a previously non-resonant system resonant. I don't think this is likely, though, because most clamp-on cores are made from ferrites suitable for EMI suppression. A common type of material for this purpose is type 43 ferrite, which has a Q of 1 at a few MHz. So this type of ferrite won't cause resonant effects like a high frequency ferrite (e.g., type 61) would.

Are you aware that a coax cable will change the impedance
from the antenna feedpoint impedance in a spiral to 50
ohms in the limit?

Roy,

Several weeks back, and confirmed by frequency sweep model runs, you indicated that minimum impedance is close or equal to the resonance point. I tuned the antenna to the frequency of interest and then used the Autek to verify the resonance point. That minimum value was 36 Ohms. I am assuming this is or is very close to the resonance point for the antenna system.

What does your running of the model show for resonance frequency? At resonance my running of the model shows close to 20 Ohms for the relatively large values of R used in the model.

Thanks - Dan

1831. 80m mobile antenna question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-28 03:39:36 UTC
From: Larry Benko <xxw0qe@comcast.net>
Message-ID: <FvSdna50paFrWJ7ZnZ2dnUVZ_s-dnZ2d@comcast.com>
Source record: 64042

I have been mobilling for years but never on 80/75m. Getting ready to
build something to mount on my Toyota 4Runner. Given the following
choices I would appreciate some advice. Assume that both my roof mount
and rear trailer mount are "perfect" and will not be the determining factor.

Choice #1:
Mount a 1" or so mast starting at the trailer hitch going vertical for
4.5' and then have the loading coil (which clears the roof line) and
finally a 6.5' whip. Base height is about 2' off the ground and the top
is 13+' off the ground.

Choice #2:
Mount a 1" mast 4' high from the top of the roof, then the loading coil,
and then a 5' whip which is vertical for 2' and then horizontal for 3'.
Base height about 6' and top height about 12.5'.

Choice #2 will have a lower ground loss (good) than choice #1 but choice
#1 being taller will have a higher radiation resistance (good) than
choice #1. For an 80m antenna which of the tradeoffs generally is more
important for an antenna this size?

Thanks,
Larry Benko, W0QE

Frank,

The Autek is remarkably close. I have used it to checkout 50 and 25 Ohm loads.
For these two values it is very close. (It is battery level sensitive.)

The couplers are a pair of M-C ZFDC 20-4's.

Thanks Dan, I had forgotten about Mini-Circuits. Their price is hard to beat. I may pick up one of the "PDC" series dual directional couplers. Incidentally your code indicates resonance occurs at 3.54 MHz. I wonder how the Autek behaves when subjected to a reactive load does it actually get close to the magnitude?

Yes, that should be correct.

> relatively large values of R used in the model.

NEC-2 shows resonance (and minimum SWR) at 3.55 MHz, where R = 16.12 ohms; NEC-4 says resonance is at 3.51 MHz., where R is 16.08 ohms. (I'm using EZNEC implementations of both.) Although small, I don't usually see that much difference between NEC-2 and NEC-4. I suspect it's because of the very low height above ground -- the two programs implement the Sommerfeld ground somewhat differently. An average gain test shows good average gain, indicating that NEC isn't having numerical difficulties.

I'm getting pretty convinced that the problem is the use of lumped loads for the inductors. With this short an antenna, I'd expect the inductor currents to be quite different at the ends(*), making the lumped load models inadequate. This can lead to pretty severe errors.

(*) due to inductor radiation and unsymmetrical coupling of the inductor to the rest of the antenna and to ground.

Good question. I will play with that. That said, based on Roy's comment at minimum the load should appear nearly pure resistive.

I just tested the Autek with 6.25, 12.5, and 25 Ohm loads.
25 read 26
12.5 read 12 - 13 - 12 etc.
6.25 read mostly 7 with an occasional 6.

I would say for non-reactive loads it is pretty close.

Tomorrow - will be to experiment with non lumped inductors. That will be a challenge.

Thanks - Dan

EZNEC v. 4.0 users should use Wires Window/Create/Create Helix. You'll get many choices, including position, orientation, various ways of specifying the pitch and number of turns, twist direction, and so forth. (EZNEC demo users can create any size helix to see how it works, but won't be able to run a calculation unless the helix is extremely simple.) In NEC, use a GH 'card'.

There should be at least a wire diameter of air space between turns, preferably several. (That is, the center-center distance between the wires in one turn and the wires in adjacent turns should be at least two wire diameters, preferably more.) If air spacing is less than 2 or 3 wire diameters, the calculated loss will be somewhat lower than reality because NEC (or EZNEC) doesn't account for proximity effect.

I suppose the right thing to do is to place ferrite cores on all the
conductors in the area. Could get expensive. I have so many wires all
over the place the job seems a bit hopeless.

Thanks for the information Roy.

Well, that's one way to solve the problem. Like the sign over my desk says, "Anyone can design a bridge that will stand up. It takes an engineer to design a bridge that will barely stand up."

Over on qrz.com, W8JI reported that he measured a 60 degree phase
shift through a 100 uH coil at 1 MHz. He also asserted that the
flux density is highest in the middle of a coil. Since the current
is proportional to flux density, that means the current in the
middle of the coil is higher than at the ends. These things are
perfectly consistent with what EZNEC reports when the distributed
network helical coil inductor is used instead of the lumped circuit
load inductor.

Essentially the only time the currents at each end of the coil are
equal is when it is installed near a standing-wave current maximum
point where the slope of the current is already close to
zero whether it be in a wire or in a coil. The phase of the standing-
wave current is relatively constant whether it be in a wire or
in a coil. (The standing-wave current doesn't rotate like a normal
phasor.) The phase shift caused by the coil happens in the forward
and reflected currents, not in the standing wave current which is the
sum of the forward current and reflected current. Not much
changes when part of a wavelength of wire is replaced by a large
loading coil. The current waveform, though warped somewhat by the
high fields inside the coil, still very roughly follows the classic
cosine shape of a wire. After all, no matter what, the current at
the tip of an antenna is zero whether it be a wire or a coil. If
a coil is placed at a standing-wave current node, the phase at each
end of the coil will be opposite, i.e. current is either flowing in
both ends at the same time or out both ends at the same time. Such
is the nature of distributed networks.

Another option is to place a choke in the mains supply for the entire station. If the RF current path is down the feedline (in common mode) and then out into the mains, you can reduce it by inserting a choke at any point along its path, and the mains supply may be more convenient place.

The mains supply would need a different kind of RF choke, of course. One option is to wind the entire mains cable - one or both live conductors, neutral and safety ground - on a stack of large toroids (bearing in mind what Roy said above, about choosing the right material). Another option is to buy a ready-made mains filter that also has an RF choke in the ground lead.

The difficulty is to organize the mains wiring so that *everything* passes through the choke. If you leave even one sneak path to ground, the RF will happily use it! Also any other lines such as phone and network connections need RF chokes of their own. If this starts to read like the things you have to do for lightning protection... why, that's perfectly true because very similar considerations apply.

Groveling on your knees under the table is a chore, and of course it's totally beneath the dignity of a Licensed Radio Armature. Well, do it anyway. At my old QTH I found it well worth the effort. Re-grouping all the mains feeds through a single filter cleaned up my mains-borne TVI, and it also reduced the computer and other noise that was coming *up* the mains.

Another very useful tool is a clip-on RF current meter. This will tell you much more than a FS meter, because at last you can *see* where the RF current is. For details, see my "Best of 'In Practice'" pages or the MFJ catalog.

Ah, yes, the Tacoma Narrows bridge. That movie played continuously in the lobby of the Engineering Building at the U. of Colorado most of the time I was going there. For anyone interested in this topic, I recommend _To Engineer is Human: The Role of Failure in Successful Design_ by Henry Petroski.

The whole trick, of course, is to stay on the right side of "barely".

Source record: 64059

Yes I should know this.. However an issue has come up in my place of work I am trying to get my head around. On a 10GHz microwave TX there is a stripline parallel to the output track that is suppose to detect forward power. Nothing strange about that. What is weird is that it appears to be roughly a half wave length (or more).

The question is this. If one hangs a 1/2 wave dipole in free space I assume it receives such that current maximums are at the centre and voltage maxiums at the ends. Is this the case whether a feedline is connected or not?

If I then take a stripline cct terminated at one end with a 50r resistor and a detect diode at the other and is a half wave long, what is the current/voltage distribution in this configuration.

What I wonder is if it is a halfwave there may be no voltage at the detect diode input. (It could be 3/4 wavelength when one factors in pcb dielectric and end loading)

Thoughts?

Cheers Bob VK2YQA

Since the ends of the 1/2WL conductor are open circuits, standing
waves on the conductor are the result. The standing wave(s) consists
of the superposition of the forward wave(s) and the reflected wave(s).
This is exactly why the forward and reflected waves cannot be ignored
(as some gurus advise) if understanding is the goal.

For a 1/2WL conductor, the standing wave has a cosine envelope with
a phase near zero all along the line because the forward and reflected
phasors are rotating in opposite directions. The current is obviously
zero at the ends and maximum in the center.

The resistor termination at one end dissipates either the forward
wave or reflected wave depending upon which end it is located. The
dipole at the other end rectifies the other wave. If you are measuring
the forward power, the forward wave is rectified by the diode and the
reflected wave is dissipated/attenuated by the resistor. I have an
old Heathkit SWR meter that operates the same way. There's two pickup
conductors, one for forward power and one for reflected power.

In short, the resistor dissipates one of the component traveling waves
thus preventing reflections while the diode rectifies the other traveling
wave, thus providing a voltage proportional to that other traveling wave.
Which wave is dissipated and which wave is rectified depends upon which
end of the conductor the resistor and diode are located.

Clearly in a center-fed half-wave dipole, if there is no load at the center, the current there is quite low, and depends on the capacitance from wire end to wire end. If you short across the feedpoint, it will be resonant and the center will be a current node.

In the case of coupled microstrip hybrids, maximum coupling occurs at odd multiples of 1/4 wavelength, and falls to zero at even multiples of 1/4 wavelength -- that is, at multiples of 1/2 wavelength. If you DON'T properly terminate one end of the coupled line, you'll loose directivity because of reflections at that end.

I suspect that if you include the propagation velocity of the microstrip, you'll find that it's not a half-wave long.

Cheers,
Tom

1853. Question regarding MFJ-1714 antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2006-02-28 21:44:39 UTC
From: junjunius@yahoo.com
Message-ID: <1141163079.201800.133290@v46g2000cwv.googlegroups.com>
Source record: 64064
Cross-posted to: rec.radio.amateur.antenna,rec.radio.scanner,alt.radio.scanner

Hello folks,

I hope that someone might be able to answer a question for me: does the MFJ-1714 have any coil in it which would serve to attenuate frequencies below the 2m amateur band for which it's apparently designed?

http://www.mfjenterprises.com/products.php?prodid=MFJ-1714

Or would this antenna serve well for frequencies below 440 MHz on a handheld scanner?

This antenna at scannerworld.com *looks* to be the same as the MFJ-1714, and it's marketed more broadly as a "3db GAIN VERTICAL TELESCOPIC BNC ANTENNA FOR SCANNERS". Any idea if this is the same antenna as the 1714? It does cost some ten bucks more than the MFJ ($26.99, as compared with $16.95 for the MFJ).

Thanks in advance for any assistance on this matter.

Junius

Maybe you would like to rethink that, Tom. Consider a parasitic 1/2WL
element on a Yagi. The currents at the ends are obviously zero. The
current 1/4WL away from the zero points are the maximum current
points. If you short across the feedpoint of a 1/2WL dipole, it will
be resonant but the center will be a current loop (antinode), i.e.
a maximum current point. The center of a *one wavelength* dipole will
be a current node.

Yes.

>current/voltage distribution in this configuration.

The point of your need at work is to insure that stripline presents a
50 Ohm characteristic as an untuned line, not a resonant line. Of
course, you can perform the same using a tuned line, but this seems
unlikely barring new details offered by you.

>What I wonder is if it is a halfwave there may be no voltage at the
>detect diode input. (It could be 3/4 wavelength when one factors in pcb
>dielectric and end loading)

And this would be reason why to NOT have it be a resonant line. I
presume there's a ground in the vicinity for both this sniffer section
and the main feed (which also needs to exhibit a characteristic Z).
Such devices are generally useful over an octave range.
>
>Thoughts?

This, of course, does require attention to factors such as pcb
dielectric as you have already taken care of end loading with the
resistor and the diode.

Im trying to build a 6dB simple colinear for my 2.4g wireless setup.
Im using a simple setup
from:

//martybugs.net/wireless/collinear.cgi

It uses a short piece of 12ga copper house wire with just two one turn
loops at 1/2 wave & 3/4 wave. I have access to a network analyzer @
work so i tried measuring the antenna'but come up with 1.4 g & 3.4 g.
No matter what i do i cant get the antenna near the 2.4 band.
Over the years Ive build many amateur band antennas of all types but
this ones got the best
of me.

Looking at the article, it appears the author did not hook up a
network analyzer to his prototype. How do you know that your network
analyzer connected to his antenna would not yield the same results.
Why not simply test the antenna in its intended application and see how
it does. Whether you are getting 6db gain over a 2.4ghz isotropic
radiator will be hard to test.
If you have built ham band antennas, you know success can be judged
in many different ways.

The 2 meter band is 144-148, not 440. The coil is a loading coil - it manes the antenna electrically longer, it doesn't cut off any frequencies.

>Or would this antenna serve well for frequencies below 440 MHz on a

It's a bit long (cumbersome), but it should work.

Richard, Cecil and Tom

I should explain the "problem" somewhat.

The transmitter designs I believe are not very good. Perhaps they were designed to work on a different or narrower frequency and were hastily adapted by beancounters instead of designers. <grin> What is happening is that at a certain critical band of freqs (around 11.2GHz) the output from the detect diode is very close to zero and hence the power control (via ALC) and calibration table dont work too well. Thinking it was a design issue I actually moved the ref diode to the limit of its pads and the problem resolved itself. The effect was of course to make the sensor length electrically shorter by doing this. I was trying to establish whether I had a 1/2 or 3/4 wavelength sensor section to maybe take it up with engineering. (No doubt for another frequency I would move it in the opposite direction)

I suspect there is also another issue whereby the resonant sensor section is actually absorbing more power than it should and dissipating it in the resistor. The effect of this being a loss of available output power at the SMA connector.

Keep in mind that I am a production line tech rather than a designer. I am not suppose to modify things, only test and align! (Am actually an IT professional but had trouble finding that line of work!)

Many thanks for your input. As usual with you gents I am going to have to work through it all slowly!

To answer you specifically Richard, the PCB is a multilayer fibreglass thing with a largish ground being under both the output and sensor striplines. I was surprised that the sensor line was so long and so close when I first saw it thinking some major overcoupling might be occurring. The tracks are maybe 3mm wide and about 1.5mm (edges) apart. I am thinking also that the 50 ohm output is not being preserved as it goes past the sensor stripline. I think the freq coverage for this model is about 10.5 to 11.5GHz. Keep in mind that this really is the frist time I have seen microwave TX's up close so my gut feelings about track sizes/spacing may be way off.

Yes, but you must have continuity between both halves of the dipole. If you disconnect the feedline leaving an open circuit gap in the dipole at its centre, you no longer have a 1/2-wave dipole of the same frequency. You have (2) lengths of wire and each has its first resonance at about twice the frequency of first resonance of your original dipole.

As I understand NEC; large errors can be introduced by junctions of dissimilar wire diameters, and in particular when the wires are at 90 deg. Therefore, when you have designed your "GH" inductors, the rest of the antenna should by constructed of the same diameter wire. This may be difficult since Dan is using two coils of significantly different Qs. I guess you could overcome this problem by varying the conductivity of the inductor to obtain the desired Q. Also, since segmentation tends to be relatively high in a helix, should segment length tapering be applied to those segments adjacent to the helix?

It's difficult to give an absolute answer to these questions, but some general comments and guidelines should help.

First, the error introduced by NEC-2 when wires of dissimilar diameter are connected is generally small, unless the wires are grossly different. This error can be minimized by making the segments as *long* as possible adjacent to the junction, which of course is contrary to the general principle that more segments are better. Even a small error can cause major changes in the pattern when the dissimilar diameter wires are in a parasitic element. EZNEC and a number of other programs have a built-in method of avoiding this problem for certain antenna types, but plain NEC-2 doesn't. NEC-4 is relatively free of this problem, but it's quite expensive for hobby use.

The Q of an inductor is determined by the inductance and the loss. The loss is a function of the dielectric, wire resistance, and radiation (which isn't really loss, but lowers Q as though it were). NEC type programs automatically account for the radiation, and it's easy to include wire loss. So assuming negligible dielectric loss, the programs should predict Q fairly accurately -- except for proximity affect. Proximity effect could be modeled in NEC by increasing the resistivity of the wires in the coil. EZNEC currently allows only a single wire resistivity for the whole model (although this will probably change in the next version). However, since the overall loss will be dominated by the inductors, the higher resistivity could be specified for the whole model without sacrificing significant accuracy. Alternatively, a number of resistive loads could be inserted in the inductors.

Segment length tapering usually isn't necessary with NEC based programs, unless there's a source near a place where the segment length changes. An average gain check should be run to determine if there's a problem.

If there is, segment length tapering is one tool which can be tried in improving the average gain.

Roy Lewallen, W7EL

Theory: "...the physics of skin effect dictate that [it] *must* happen
[*]somehow[*]...

Now, compute the consequences of the theory to see if it is right what
it would imply.

Compare those computation results to experiment. If they disagree, the
theory is wrong.

If you can't apply this procedure, your statement cannot be verified
scientifically.

I can't prove this but I suspect there will be very little difference.
The wavelength on 80/75 meters is so much longer than the car body that
going from a low mount to a high one will be almost unnoticeable.
Ground loss will be about the same because the capacitance between the
car body and ground is the important factor and does not depend on
where the whip is mounted.

What will matter greatly is the Q of the coil. Make it inherently as
high as you can and keep it away from metal parts of the car body.
Resonate it and match it and you will have lots of fun. 80/75 is a
great band for mobile and much underused.

What we found at the CA shootouts is that when the bottom
section runs closely parallel to the vehicle body, as it
does with a trailer hitch mount on an SUV, the field
strength is much lower than if that bottom section is
in the clear, e.g. mounted on the roof of the SUV. Of
course, roof mounting creates a different set of problems.

Rubbish!

The word 'theory' has two different meanings - so different, they are almost the opposite of each other. And you are using the wrong one.

You are using the layman's meaning of 'an unproven speculation' - but in science, the word means almost the exact opposite. A scientific theory is "a well-substantiated explanation of some aspect of the natural world; an organized system of accepted knowledge that applies in a variety of circumstances to explain a specific set of phenomena" [1]. (In scientific language, an unproven speculation is called a hypothesis or a conjecture. It is specifically *not* called a theory.)

A *scientific* theory explains the underlying reasons for a huge number of different experimental and practical observations, so that they all mesh together and support each other. Theory supports observation; and observation supports theory. Equally important, the outside edge join up seamlessly with the theory and observations about related areas of science. This means that scientific 'theory' is vastly more than mere speculation: it has the power to predict what will happen in cases we haven't even looked at yet.

As I said, the crossovers between strands of braid are hard to visualize and predict in detail - but that is entirely our problem. Our lack of understanding doesn't change the way things work.

There is no absolute proof that the skin effect will apply to braided strands, but this is only a very small gap in our knowledge. At both

sides of that gap are situations where we're completely certain it does apply. Moreover, there is no rational reason to suppose the skin affect might fail to apply to braided strands.

Based on that solid body of theoretical and practical knowledge about the skin effect, it only needs a very small amount of additional speculation to bridge the gap in our knowledge about braid. Applying what we do know to what we don't, it immediately gives us a clear and simple explanation why the RF resistance of braid is greater than a smooth surface, and why it increases dramatically when the braid is corroded.

This is a perfectly normal application of scientific logic to bridge small gaps in our knowledge. Since nothing can ever be proved in absolute terms, I must philosophically decline your challenge to waste time on modeling it in detail :-)

In terms of strict logic, the onus is on you to find a way to disprove it and to offer something else in its place. Good luck with that.

Hi Richard

>>I was surprised that the sensor line was so long and so

> On the order of 1.5 cM?

It is a "U shape". The section parallel to the output stripline is maybe
1cm long (going from memory). The leg length may then put the total size
at more like 2cm.

>>I am thinking also that the 50 ohm output is not being preserved as it
>>goes past the sensor stripline.

> What does that mean?

I am suggesting that given the proximity of the sensor section it
presents a significant Z bump. Like I said I dont have a feeling for the
track dimensions for stripline etc at microwave. Not that it wouldnt be
difficult to look it up mind you!

>>I think the freq coverage for this model

How thick is the board material, and what material is it? The propagation velocity depends on the permittivity (dielectric constant) of the material. The impedance depends on the material and the spacings and trace widths. Presumably there's a ground plane behind the microstrip lines (else they aren't microstrip). There are many web sites that will let you play with microstrip designs, and some that will give you the response of a coupler like you're describing. Do a web search for things like "directional coupler" and "90 degree [microstrip] hybrid". But if you plot the coupler's coupling versus frequency, you'll find it's zero at DC, increasing to a fairly broad maximum when the freq makes it 1/4 wave long (accounting for the velocity factor), and falling again to zero at twice that frequency where the line is 1/2 wave long. That pattern repeats. If you account for the response, the coupler is useful over a broad range of frequencies, as the directivity stays good even as the coupling decreases (if it's accurately made). You can extend the frequency range (make the peak even broader) by "tapering" the coupling. (Easier to see in a picture than trying to explain in words...basically a cascade of sections, with the center one coupled most closely.)

A point to note: if you make the coupled line say 5/4 wave long at 10GHz, it will couple nicely at 10GHz, but you only have to move by 2GHz in either direction to hit a null at 4/4 and 6/4 wave long for the same physical line length. But if you make the coupled line 1/4 wave long, then you don't see a null till 20GHz, and the coupler should be quite useable between 8 and 12GHz. You can make the coupled section short by leading the ends to the 50 ohm load and the diode detector away from the coupled section, at right angles to it, so you don't have to worry about the length of the resistor and the diode adding in some difficult-to-calculate way to the overall length. Perhaps they already are done that way, but from your description that's not clear to me.

Cheers,
Tom

Owen has provided a nifty transmission line analysis tool at:

http://www.vk1od.net/tl/tllce.php

By clicking on a particular type of transmission line
and doing an analysis, some of the important characteristics
of that particular type of transmission line will be displayed
along with the results of the analysis.

The ARRL Handbook contains a lot of information on the
different kinds of transmission lines as does the ARRL
Antenna Book.

"Wirebook IV", available from www.thewireman.com, is probably
a good read and reference. I have "Wirebook III" with 60
pages of information. "Wirebook IV" contains four times that
number of pages. When I am looking for information on
transmission lines, I reach for "Wirebook III" which is
never out of reach at my QTH.

What we found at the CA shootouts is that when the bottom
section runs closely parallel to the vehicle body, as it
does with a trailer hitch mount on an SUV, the field
strength is much lower than if that bottom section is
in the clear, e.g. mounted on the roof of the SUV.....

I often wonder about this myself, but never get around to trying a
bumper mount. In the past, I've always preferred to have the lower
mast and coil as clear of the body as possible. But on the other
hand, if I mounted the base on the bumper, I could have a longer
mast below the coil. It's hard to decide which would be better on
paper. But...On my "play" truck, I decided to go whole hog. I
mounted the base of the antenna on the rear pillar of my cab,
back behind my head. The base of the antenna is appx 64 inches
off the ground. Yes, it kicks butt... But I sometimes wonder how
it would do with the bumper mount, and longer lower mast. The
problem is I have campers on both of my trucks, and have always
been afraid to have the lower mast right up against the back tailgate,
and camper. It's hard to decide of the longer antenna would outweigh
the higher mount, and shorter antenna. I think really the only way to
know for sure is to actually try and compare both.
But in the past, and present, I'm a "high mounter" as far as mobile
whips.
BTW, I was out camping in Utopia TX about 2 months ago, and had
the chance to really give that truck and antenna a good workout.
It was browning the food. I was S9 plus to all TX stations, and even
S 9 to a Salt Lake City puter receiver listened to on the internet.
That was 80m...On 40m, it's even better. Course, that antenna when
parked is 14 ft tall, and has the coil at 8 ft from the base. It's 11
ft
tall in the driving mode. Even the short version is tall, when mounted
on the cab of that truck. The radio was the 706 barefoot. I use no
amp when mobile. I do know it's really bad news to have the coil
near body metal. But I've never had that problem yet on my various
vehicles.

Hi Bob,

DC is so remote from the application as to be only an approximation.
There's also the prospects of reactance to consider too. When you say
you can see a frequency dependency, you are almost guaranteeing that
"tuning" has been injected into an otherwise wideband design.

From your position in the company you have two paths:
1. Announce the design is FUBAR, or
2. Find an ad-hoc solution and forget theory because you are in no
position to re-engineer the design.

#2 is a dangerous path to take for the sake of the company's
perspective, although it may be more politic if the design department
is populated with prima-donnas.

#1 will accomplish one of two things, the design will be corrected, or
you will be educated - possibly both. Most designers appreciate
hearing what your experience has revealed. Most of my techs enjoyed
pounding my designs to find the weak seams. One fellow had a small
transistor radio that he would put on top of the microprocessor to
listen to the software running. He could always tell when one of my
patches went south.

What worked like a charm for me was using the trailer hitch
hole on my GMC pickup and removing the tailgate. I looked
for a fiberglass aftermarket tailgate but couldn't find one.

That seems to match up with various peoples' experiences that I've heard. Close spacing in this way makes the signal weaker, and also seems to make the antenna more difficult to tune/match properly.

This also makes sense from an engineering point of view. The closely-parallel spacing of the bottom section and the metal vehicle body would form a transmission line of sorts. This transmission-line section would not radiate much (or efficiently) - its radiation resistance would be quite low. As a result, the antenna's feedpoint impedance would be lower than otherwise (requiring a more aggressive impedance step-up of some sort to match a 50-ohm line).

The coil and whip would be above the body, and would still be able to radiate, but you'd be left with something akin to a bottom-loaded whip with no high-current radiating section, rather than a center-loaded radiator with a low-loss high-current radiating section below the coil.

In effect, a close/parallel mounting of this sort would seem to sacrifice much of the radiating power of this type of antenna.

Just purchased a (tri-band 2, 1.25, .7 meters) Kenwood TH-F6A HT and was wondering what I should use for a base antenna that will be over 60ft high (bet I'll get tons of intermod). One thought is to purchase the best tri-bander available or, perhaps there is too much compromise with an all-in-one. Would you use a dual bander and a mono, which band is the dual & which the mono or 3 monos? Of course with anything other than a tri-bander, a triplexer will be needed. Oh what trying decisions a ham must make! Any comments most welcomed.

Hi West,

A simple tribander should be able to hit a similar tribander, or at
least a quarterwave just as high 20 miles away. Repeaters should be a
breeze to hit unless you are DXing garage repeaters. I can't see that
you need more gain nor complexity unless its to make up for line loss
climbing that tower. In that case, add a brick amplifier at the input
to the line.

If I were dead set on all 3 bands, I would use a seperate ground plane
antenna for each band, and an antenna switch. The ground planes are
small.

With that in mind, I have a friend who has a Ford Exploder--I mean, EXPLORER :) --- with his DK3 mounted on a homebrew mount level with the rear bumper. The bad part of it (IMHO) is the loading coil is level with the body about where the rear window is and about 8 inches from the body. I mentioned to him that it would be better to get the coil up in the clear above the truck, but he is says he can't get in his carport. Well, what about this: move the coil UP to clear the body and use a shorter whip? IOW, faced with the lesser of two evils, which would be better. Left as is with longer whip and putting up with the loss caused by proximity to body metal, or coil clearing the top of the truck and a shorter whip--even it it has to be 5 feet instead of 6 1/2? I voted for the higher coil and shorter whip. What say ye? :)

I am assuming you mean a 2 element beam with both elements driven.

If so, I would recommend trying to make a 2 meter version of Roy W7EL's
version of the ZL special. I just messed around with his downloadable
program for 15 minutes and got a reasonable version hacked up for your
frequency. The impedance wasn't perfect, about 1.5 at best and about 3
to 1 SWR +-1.5 MHz, but you are receive only, so that's not a big deal.

Heck, he may notice this response and tell you he's done one and what he
came up with for lengths.

The important characteristic is common mode impedance. Tie the two input conductors together and the two output conductors together, and measure the input-to-output impedance. This can be done in various ways, most easily with an antenna analyzer, or by other means. The higher the impedance, the better. 1000 ohms seems to be a good number to shoot for, with 500 ohms probably being ok for most applications. The angle of the impedance doesn't matter unless you're running high power, in which case it might be necessary to keep the impedance more reactive than resistive to prevent excessive core heating.

A good choke balun for multiple band use will have a high common mode impedance on all bands on which it'll be used. Narrower band ones can be connected in series as an alternative.

~~~~~~
No doubt that is correct. So how about this: I have a '95 Thunderbird which I dearly love and don't want to cut holes in. I've been think of going to a welding shop and having a metal piece made which I could bolt to the frame in the back and which would stick out about six inches or so behind the rear bumper, and installing a ball mount on it. This will keep the lower part of the antenna about a foot away from the body and allow a nice, long whip overall. The loading coil would be in the center, homebrew of course. :-)

And not a hole in sight.

Comments?

Frank,

I observed by playing with the relative inductor values on the vertical segment
and the radial elements that it was possible to move the relative feedpoint.
This supports tuning the antenna by either inductor.

Reg's c_poise program predicts a 75 uH loading coil.

I am excited with prospect of coil models.

Thanks - Dan

Dan, I have been trying to replicate your inductors with NEC. It is a bit tedious, just guessing wire gauge, coil diameter etc., to obtain the desired inductance and Q. What are the physical dimensions of your inductors?

Have you had any luck with GH? You may have a problem with 4nec2 since you must have a GM card along with the GH.

I'm not sure why, but most amateurs don't seem to realize that the whip isn't an "antenna" and the car "ground", but each is half of a dipole-like antenna. The car part is often much more important with regard to radiation characteristics and efficiency than the whip part. With the arrangement you suggest, the antenna consists of a vertical wire -- the whip -- and a fat, horizontal "wire" -- the car. Whatever current flows into the whip, an equal current flows over the outside of the car, originating at the base of the whip.

Any antenna with a low horizontal wire will be quite lossy, because the wire's current will induce a heavy current in the lossy ground beneath the wire, or car.

The best arrangement, as others have pointed out, is to mount the antenna right at the center of the top of the car. This makes the car "wire" vertical, a much more efficient arrangement, which the "shootouts" consistently show. You'll also find that larger trucks, which effectively form a longer vertical "wire" for the car part, outdo smaller ones for the same whip.

Of course, sometimes you don't have any choice, and you just have to do the best you can. I once had a bumper mounted antenna consisting of a CB whip base loaded with an inductor wound on a powdered iron core to resonate on 40 meters. The car was a VW Squareback, so the antenna had the increased disadvantage of proximity between the square back and the antenna. As others have pointed out, this can reduce efficiency farther. Yet I had a successful QSO with JA while driving down Highway 101,

running 8 watts, CW. So you can still communicate and have lots of fun even with a very sub-optimal system. But anyone wanting to improve his system has a much better chance of doing it if he has a basic understanding of how the antenna really works.

For his application, shoot for the best F/B ratio -- that is, for element currents as close to equal and the correct phase -- as possible. The forward lobe of this antenna is broader than a 3 element Yagi. It would work best as a direction finding antenna by determining the direction of the null. Quite a bit of mismatch should be tolerable unless signals are extremely weak, but if an adequate match can't be achieved, it's simple to remedy with a simple matching network.

> Heck, he may notice this response and tell you he's done one and what he
> came up with for lengths.

Nope. I've never had occasion to design an antenna for 166 MHz. One designed for 2 meters (which I haven't done either) won't work satisfactorily at 166.

> Rubbish!

No, it isn't. That was a paraphrase from, "The Character of Physical Law," by Richard P. Feynman, page 156, half-way down. Also from "The Character of Physical Law," bottom, page 156, "It is scientific only to say what is more likely and what less likely, and not to be proving all the time the possible and impossible."

Therefore, it is more likely what Richard P. Feynman said about scientific theories is right and what you said about scientific theories is wrong.

~~~~~~

Well, maybe. The problem is, the higher the mounting point, the shorter the whip has to be to be legal to drive down the road. If your car was 13 feet five inches tall, your whip could only be one inch long. How efficient would that be on 80 meters? The point being, everything is a tradeoff of one thing for another. If the shootouts say a rooftop is best, ok, but I have to say I'm surprised. At a relatively low frequency like 80 meters, the car body is more of a coupler to the earth rather than a real "ground" of it's own. Given that, then the longer the whip part, the better.

HF mobile antennas are a fascinating subject and one of these days I will set up a "shootout" range on my 2.5 acres here in the desert and do some shooting of my own.

Here's a clue: if even Feynman needed a whole book to cover the subject, is there any possibility that your "paraphrase" from half-way down one page might be incomplete, inaccurate or misleading?

The rubbish arises entirely from your habit of snipping bits from here and there, and quoting them out of context. The history of this thread shows that each time someone makes a considered reply, bringing back the whole context, you snip it all out again.

Enough of that game.

==========

Ten or more turns of twin, 18 awg, stranded, speaker cable is even
better.

Easier to make and has higher choke impedance and lower loss.

I don't know why you mess about with coax.

Reg.

The only way to improve on that on 75m would be to mount
a piece of sheet metal on fiberglass poles connected at
the ends of both bumpers. The piece of horizontal sheet
metal, located 13.5 feet from the ground, would have the
same footprint as the T-bird and would be used as the top
hat. You do want optimum performance don't you? :-)

1913. 2m omnis and radiation takeoff angles - importance

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-02 13:30:39 UTC
From: Bob Bob <bob3bob3@cox.net>
Message-ID: <0l8jd3-mag.ln1@p400bob.personal.cox.net>
Source record: 63975

Hi NG

About ready to model and build a medium 2m antenna system. Probably run a EDZ with 5/8 elements off one side of the mast for vertical and a three element wide spaced thick element quad for horiz on the other side. The mast mount will form part of the model when I get to it. (Hoping for a cardioid pattern from the EDZ)

Main element material for both antennas will probably be 1/2" copper. (That will make the quad interesting to support!)

Sticking to the vertical system I am wanting to get a handle on how important the "problem" of desired low angle radiation is and what traps one should avoid. I am aware of the mast/coax decoupling issues. I also believe that the narrower the vertical beamwidth (or rather the less downward radiation) the less the ground reflection problem will be.

Also wondering if adjusting phase delay or amplitude variations between the 5/8 elements would be useful in lowering the pattern. (Something I will also be modelling) Feed would probably be a 4:1 coaxial balun.

Height will eventually be about 30ft above the house roof.

Any thoughts, ideas and debunking most welcome

Cheers Bob W5/VK2YQA

The optimum Z0 for the wire that is used is the square root
of the product of the input impedance and the output impedance.
I vary the length of my ladder-line to accomplish resonance
in my antenna system. The impedances seen at the output of
my balun averages 50 ohms. Thus, the optimum Z0 for my
balun wire is 50 ohms. Magnet wire will do that but speaker
cable won't. Ten turns of RG-400 is really convenient. I use
RG-400 for everything inside of the shack. All the 1/2" dia.
stuff is outside.

Frank,

A 'target' coil is 300mm x 300mm of 5/16 copper tubing. It is about 50 feet of tubing, a .5 pitch, and should be close to 75 uH. This should be close. From there simulation should show the best performance between varying the coils.

Thanks - Dan

Roy Lewallen, W7EL wrote:
"I`m not sure why, but most amateurs don`t seem to realize that a whip isn`t an "antenna" and the car "ground", but each is half of a dipole-like antenna."

Not exactly..

In a common balanced dipole, each half has the same current quantity and direction, though in one half the current flows toward the feedpoint while it flows away in the other half.

From such a dipole, both its halves contribute equally to its radiation.

Action of a common ground plane is different. When its balanced radials are perpendicular to its whip, radiation from its radials zeros out leaving the whip to do all the radiation. Ideally, a whip mounted on a vehicle or directly on the earth behaves the same. It is the whip which radiates.

An antenna is also called an aerial. It is defined as that part of a radio station which radiates or receives radio waves into or from space.

An antenna ground system is defined as that portion of an antenna system closely associated with the earth and including an extensive conducting surface which may be the earth itself.

Most radio amateurs have it right.

A ground plane is a poor model of how currents flow along a car body.

Consider an antenna mounted on top of a car. From the base of the antenna, the current flows equally in all directions away from the base of the antenna, like a ground plane. This current doesn't contribute much radiation, for the reasons you state. But then it reaches the edge of the top of the car and flows downward. All the portions of the current are now flowing the same direction, and their fields don't cancel but add in phase. The net result is the same as if it were just flowing down a fat wire the height of the car. If the car is eight feet high, the field from the car will equal the field from an eight foot whip. In fact, unless the whip is top loaded to make the current uniform, the car will radiate more than the whip, because the capacitance of the car to ground will tend to give the car a uniform current distribution, like a top hat does to a whip. This will increase the radiated field strength from the car.

Now consider a bumper mounted antenna. The current will spread from the base and proceed around the car. More will probably flow on the bottom than the top and sides due to coupling with the ground, but all portions will be flowing in the same direction and all will radiate. There is no place on the car where the current distribution or flow pattern resembles current on a ground plane.

The problem here is that the currents don't care how you define things.
They flow where the physical laws dictate. Defining "ground" doesn't
make them behave differently.

> Most radio amateurs have it right.

If your view represents that of most amateurs, they don't.

I think if it is too strong it will affect your eyes first, ears then nerves/brain last. There are lots of safety precautions for wx radar on aircraft and they are generally are under 10kw for small planes, x band radar. Large jets, c band. Then there are fighter aircraft whose targeting radar has been know to kill small animals around the runways. But those are out of favour now, low power is in.

Boy Richard, you sure missed the boat on that one!

Roy is quite correct in stating that a vehicle's body behaves as one side of a dipole. A lopsided dipole to be sure, but one half the antenna just the same.

A number of years ago I did a study using NEC modeling comparing VHF mobile whips (1/4, 1/2 and 5/8-wavelength) mounted on different vehicles. I created wire frame vehicles models for a full and mid-size passenger cars, a small pickup truck and an SUV. The results for the same antenna mounted top-dead-center on the different vehicles was quite noticeable sometimes substantial.

An article I wrote on the subject can be viewed at:

Seems the truth might lie somewhere in between. If the ground
plane of a vertical antenna is near the ground, there are
losses. If the ground plane of a vertical antenna is located
1/2WL above ground, the losses are a lot less. I'll bet that
if the vehicle were located 1/2WL in the air, the efficiency
would increase.

Source record: 63892

There have been recent discussions about the interchangeability of coaxial plugs and sockets, their dimensions and their impedances. But, as usual, the magnitude of the electrical effects is never mentioned. Without numbers nobody knows what they are talking about.

A coaxial connector is a very short length of transmission line but at UHF and microwave frequencies it is an appreciable fraction of a wavelength. When 1/4-wavelength long it has the property of transforming a mismatched termination to another value. When 1/2-wavelength long the input impedance repeats the value of the termination. The SWR on an adjacent line is a function of the input impedance.

What is the effect of using a 75-ohm coaxial connector in a 50-ohm system?

What is the effect of using a length of transmission line of 50-ohms nominal impedance when it is actually 53 ohms?

With mixed values of line Zo at what high frequency does the SWR and reflection loss become excessive?

Program CONNECT.exe calculates the effect of inserting a length of line in a system of different Zo. Differences can be large or small. Line length can be physically very short.

For a given frequency, mismatched Zo's and a velocity factor, input impedance, SWR, reflection coefficient and reflection loss are calculated. (Reflection loss is sometime known as mismatch loss).

The program is worded in terms of a connector mismatch but has other applications.

Input data can be varied in small increments from the keyboard while observing the effects on calculated values. Download CONNECT from website below. It has entertainment, educationaal and practical value. Amuse yourselves!

Danny K6MHE wrote:
"Boy Richard you sure missed on that one!"

A broadcast tower over a perfect ground system is the source of radiated energy even though its image in the ground system produces a pattern which behaves as if there were a dipole, the lower half of which is buried.

The earth is not radiating. It is conducting. The tower above the earth is the source of radiation.

Every ground radial in the broadcast system (usually all 120 of them), has a twin running in the opposite direction. All radials are tied together at the base of the tower. So the current in the radials all starts out in the same phase and stays roughly in the same phase as it progresses outward. It declines in magnitude away from the feedpoint. That`s the reason ground radials don`t need to be unlimited in length. You don`t need radials after the current plays out. As current travels in opposite directions in the groind radials. the fields they prodoce add to zero.

The two halves of a dipole are fed with opposite polarities at their feedpoint. this puts the two halves running in opposite directions in-phase. Their fields thus reinforce.

A 1/4-wave ground plane in free space has the same power gain as a center-fed 1/2-wave dipole.

The matched power radiated by either ground plane or dipole is the same, but the resistance at the feedpoint of the ground plane is only 50% that of the dipole. Radiation resistance is defined as the resistance at the high current point of the antenna unless otherwise specified. Radiated power is (I) squared times the radiation resistance.

Danny did not specify where he thought I erred in my previous posting. I said that a whip mounted on a vehicle is not exactly like a dipole. I meant that the whip did most of the radiating because it carried a concentration of current in the same direction while in the car body the current is dispersed in various directions, some of which canncel in their effects.

I still insist that is the case.

Best regards, Richard Harrison, KB5WZI

Having trouble producing a good model Dan. NEC 2 indicates Qs which are >5000, but no warnings or errors. I can run it in NEC 4.1, single, and double precision, but I get over 400 warnings in the NEC output file; such as:

SEGCHK: WARNING - SEGMENTS 1 AND 271 CROSS AT A MIDPOINT WITH SEPARATION LESS THAN THE SUM OF THEIR RADII

SEGCHK: WARNING - THE CENTER OF SEGMENT 1 IS WITHIN THE VOLUME OF SEGMENT 271

These warnings are particularly strange since, for example, absolute segments 1 and 271 are almost 12" apart in the model. Will see what I can do to correct the error.

73,

Frank

The code I am using is as follows:

```
CM Inductor Q Calculation
CE
GH 1 300 1 12 6 6 6 6 0.3125
GW 2 5 6 0 12 0 0 12 0.3125

Q. How can a car body which is a "small fraction" of a wavelength act
like one half of a dipole?

A. It can't.

Q. Well, what does it do then?

A. It acts like a short piece of wire leading from the bottom of the
whip to the actual ground plane, namely the earth itself.

Q. Does that help any?

A. Probably a little, but remember the piece of wire (the car body) is
only a few feet long. Not very much on 80 meters.

Q. Thanks, I get it now.

A. You're welcome.

Actually it is acting as one half of a dipole. It is just a non-resonant
half of a dipole. Remember "di" means two.

NEC-2 and NEC-4 have different formats for the GH 'card'. This is the NEC-2 format, which will be interpreted differently by NEC-4. See your NEC-4 documentation for the correct NEC-4 format.

I'm afraid people are getting too hung up by trying to squeeze everything into various pigeon holes like "dipole" and "ground". You'll have to think beyond those narrow and poorly defined and understood categories and look at the basics of antenna operation in order to understand what's happening.

The field radiated from a conductor is determined by two things: the amount of current on it, and the length of the path the current takes. Theorists have known this for well over a century. The most sophisticated antenna analysis programs break the current paths into very short pieces ("segments"), calculate the current on each piece, and then calculate the resulting field from the product of the current and the segment length. Fields from various parts of the conductors can cancel or reinforce to any degree. (Mathematically, they add vectorally.)

If you don't or can't believe this, you needn't bother continuing.

For those still reading, let's imagine a 16 foot vertical wire with a tiny 3.5 MHz signal generator at the center. This is known in textbooks as a "dipole", but how things behave aren't dictated by what we call them, so feel free to insist it's a "seagull", "pizza", "xfppftm", or whatever makes you comfortable. The signal generator has two terminals, and any generator must have equal currents in and out of its two terminals. If you don't or can't believe that, brush up on Kirchoff's current law. If that doesn't do it, there's no need to continue further.

Let's suppose the generator is producing one amp RMS of RF current. If, say, 0.2 amp is flowing upward out of the top terminal at a given instant, 0.2 amp is flowing upward into the bottom terminal at the same instant. By inspection, one amp RMS is flowing upward in the vertical wire immediately above and below the generator. By a number of techniques, we can show that the current decreases nearly linearly from the center to the ends. That is, four feet from the center, either above or below the source, the current is 1/2 amp. At the antenna tips, the current is zero, which we should expect: there's nowhere for it to go.

It should be obvious that the wire above the source is radiating the same field strength as the wire below the source -- for each little piece of the wire above the source there's a piece below the source carrying exactly the same current. And as it turns out, the fields from all parts of both wires add completely in phase directly broadside to the wire, and only partially in phase in other directions. So at least directly broadside, we can say that the contribution from each wire is equal and proportional to its total field strength.

Ok, now let's make one of the wires "ground" and the other a "whip", because we like to do that, right? Let's call the top wire a "whip", and bottom load it. We add an inductor (very small, physically, to avoid adding another dimension to this analysis) between the signal generator's top terminal and its connection with the upper wire. We can make the inductor the proper value to make the upper wire/inductor self resonant if it were grounded, or we can make the inductor about twice as large to make the whole dipole resonant. It doesn't matter. Now let's see what happened to the radiation from the "whip" and "ground" wires.

There's no change whatsoever! The currents are exactly the same as they were before, on both wires. They still taper from the center to the tips as before. They both radiate equally. All we've done is change the impedance seen by the generator. If you don't believe this, perhaps you can explain why they won't.

Next, let's replace the lower wire with a cylinder like a tank, say 10 feet in diameter but still 8 feet high. What happens then? Surely it must now be "ground", and "ground" doesn't radiate, does it?

Well, it does radiate. The one amp flowing into the bottom generator terminal spreads out radially over the top of the cylinder. Although the current density decreases as we move out from the center, the total current also decreases. If only the cylinder top was present and the rest of the cylinder missing, the current would drop to nearly zero at the edge. But because of the presence of the rest of the cylinder, the current at the edge drops to about half the value at the center. The half which remains flows down the cylinder sides. This would result in the field from the cylinder being about half the field from the "whip" if the current decreased to zero at the bottom of the cylinder as it does at the top of the whip. But the current along the sides of the cylinder doesn't drop to zero at the bottom of the walls because it can flow onto the bottom of the cylinder. The average current on the whip is 0.5 amp, and on the cylinder (from a model) about 0.35 amp, so the cylinder's field is about 3 dB less than that of the "whip". Not quite what most of envision when we think of a "ground".

If we top load the whip with a 10 foot diameter top hat, its average current increases to about 0.9 amp. But its presence also reduces the amount of current drop from the center to the edge of the cylinder top due to mutual coupling. The end result is larger current along the cylinder sides and very nearly the same field strength ratio between the "whip" and cylinder.

So far this analysis has taken place in free space. What happens if we put the cylinder bottom just above the ground, say six inches? Now, surely, the cylinder is "ground"! But the current still flows down the sides and radiates just like the old original vertical lower wire did. And putting the bottom close to ground increases the current along the sides! The coupling between the cylinder bottom and ground acts somewhat like a top hat does to a whip, and increases the average current. Instead of 0.35 amp, it increases to about 0.42. Now the cylinder's field is only about 1.5 dB less than that of the "whip".

I hope this has encouraged at least a few people to think a little
before declaring every conductor to be either an "antenna" or a "ground
plane" and assuming that by doing so they'll somehow cause it to behave
in some predetermined and only vaguely understood fashion.

In a strict sense you are correct, but in the context here where one
half of the dipole is an eight-foot whip and the other half is four
feet of car body, we don't have much of an 80 meter antenna without the
coupling from car body to earth ground.

A very good explanation, thank you Roy.

However... in your example of the giant tin can in free space, the top of the tin can is acting like a ground plane, the side is acting like an antenna and the bottom is again acting like a ground plane, just as we have been saying. When this model is transferred to a car body, the bottom of the car, in addition to the above, is also acting like one plate of a capacitor coupling the signal to the earth below it, commonly known as "ground". If someone disagrees with this I believe we have a problem with semantics more than physics.

In other words, we are arguing over nothing.

Howdy Dan:
Thanks for the info on "Mobile Vhf Ant.pdf", very interesting stuff.
I was checking out the rest of your site, and found an interesting pdf on the "Skeleton Sleeve Antenna",
and it's similarity of the J-pole, and you state that the distance from the 1/4 wave elements, and the 1/2 wave
element is not that critical. I have heard this before about the elements on the J-pole too, but what I don't understand
is why this dimension is not critical, it is an electrical path that should be subtracted from both elements, right?
Is it correct to shorten both elements by 1/2 of the dimension between the elements?

No argument here Bill. The point I guess I was trying to make is that a
dipole antenna system is two elements no matter what you make them of.
I use a Hi Sierra screwdriver antenna on my Honda Element. Even though
is is an impressive construct I don't harbor any illusions that it is an
efficient radiator. The body of the car is longer than the length of the
screwdriver, coil and whip. I have also used an Outbacker. Some say that
is a good antenna for it type, I have not had that good of a result with
it. Of course I am using my mobile for Civil Air Patrol and the
Outbacker does not fit that frequency very well on the precut tuning jacks.
I have found this thread to be interesting but I think that is had
passed that point.
I do not consider myself to be anything other than an interested amateur
and always consider your comments with great interest. Thank you for
your personal comments.

Although my "evidence" is purely anecdotal, I've sure had good success
on 80 meters with a pair of hamsticks mounted horizontally (one pointing
forward and one backwards) about two feet above my picup cab (which has
a metal "topper" behind the cab at essentially cab-top height). I've
always assumed it was acting much like an NVIS dipole....

Thanks Roy, now you mention it I do remember that there are some differences. Should have checked with my manual before running it instead of just cutting and pasting NEC 2 code. Made the appropriate correction and it is now working with a reasonable correlation with NEC 2. Heck, now I just noticed I had entered the wire diameter instead of its radius!

Cecil, W5DXP wrote:
"The only way to improve on that on 75m would be to mount a piece of sheet metal on fiberglas poles connected at ythe ends of both bumpers."

Kraus gives some support to that idea. Cecil has the 3rd edition of "Antennas" In that edition, there is a "Disc antenna" on page 720 with some similarity to cecil`s suggestion.

The "flush-disk" antenna, (d) in Figure 21-11 is said to be comparable to a 1/4-wave vertical in performance, but has no projection. It could be covered with a dielectric sheet, make no noise in the wind, and break out no fluorescent tubes in parking garages. But, at 75m, the 0.3 lambda dia. depression to contain it would measure 22.5 meters. That woud require a vehicle that was very large indeed. At VHF and UHF it could be very practical.

Best regards, Richard Harrison, KB5WZI

The basic facts are: Any commercial civilian Xband Radar will NOT even
come close to approching FCC RF Radiation Biologic Health Maximum
Radiation Power Densities even if you are right next to the antenna.
You are more likely to get hurt by the rotating antenna hiting you
in the head than from the RF Energy coming out of the antenna.
Wx Radar on Commecrcial Aircraft usually are left in Standby Mode
untill the aircraft has taxied onto the tarmac beside the active runway.
Eve if they were activated, most xBand versions still don't have the

Power Density one foot in front of the antenna to approch the FCC RF
Radiation Biologic Health Maximum.
Military Radars are a totally different beast altogether, and there are
very strict operational rules for when they can be operated inside US
Water and Airspace.

I'm getting ready to mount a dipole between two trees in my backyard.
Both are large sycamores and I plan to have the dipole about 60 feet up
(max).

In an ARRL publication, there is a description of using a bow and arrow
to get over the branch desired.

This is the method I guess I'll try (can't climb these trees).
Once I have the nylon fishing line over, I'll need to hoist up a nylon
rope attached to a pulley attached to the antenna itself (I mean, of
course, the support line attached to insulator).

I can't figure a way to hoist all this up without, say, 120 feet of
nylon rope in an inverted U plus the weighted support line attached to
the antenna. Yes, I can use a slip knot but I still end up having 60
feet of rope draped from the tree. Should I find a way to cut the nylon
rope near the branch? Just tie up the hanging rope?

It seems necessary to "waste" as much as 60 feet of rope in either side.
If I support the center insulator, then double that.

Is there a better way?

John

PS, Sorry, I couldn't find a way to insert something with imaginary
numbers (hi)

I interpreted your comments and those by some others as claiming that radiation from the car is insignificant, and that it therefore isn't effectively part of the antenna. I attempted to show that this isn't generally true. I also showed that coupling to the ground actually increases radiation from the car. So either I've convinced you by my illustration, or I misinterpreted your earlier remarks.

I'm not sure what the problem is, yes, it takes a bunch of rope if
you can't climb the tree.

I usually don't bother with pulleys as I prefer to get the antenna
up as high as possible. You will lose 15-20 feet of height (or more)
using a pulley compared to not.

That may have some validity in the VHF and higher ranges, but on HF - particularly on 80 meters - a car body's size is a small fraction of a wavelength (as is the whip portion). Consequently the vehicle body acts like the one half of a dipole antenna. Slightly lop-sided yes, but a dipole just the same - just as Roy stated.

I am working with some guys on ambient noise measurement in a pre BPL scenario.

They are using FSM (http://www.vk1od.net/fsm/) to make field strength measurements using a known comms receiver and a Carolina Windom (CW).

We need to form a view on the CW antenna system losses (radiator, ground reflection, isolator, matching unit, feedline, ATU.

Has anyone built and calibrated NEC models for the CW, or have they measured reliably feedpoint impedance on the various bands.

This is not a troll, and I don't want to excite a war over the claimed performance of the CW, I am not interested in anecdotal evidence or QSO evidence as to whether they "work".

I see that there will be significant issues in modelling the "secret" components of the CW unless someone has worked out an RF equivalent circuit of those components (the isolator and matching unit).

Thanks...

Owen

On my plane the radar is 7.6 kw (xband). The manual says not to use it on the ground especially around people. Also they have been know to cause some sort of sparking on metal so fuel trucks are to be avoided. Shop people are cautioned to make sure it is not emitting if in stby mode, some do. The display will say STBY, the antenna not panning, but it is emitting. Go figure. Small airplanes have xband not because it is wimpy but because of antenna size constraints. These are 10 ro 12 inch diameter "flat dish" antennas. Lots of waveguide-like openings on it. Extreemly directional. And this is a small 6 seater plane.

Large weather radars, ground based are sband. Big antennas.

In the late 80's many radars dropped down to under 10 watts. Most under one watt. Mainly due to improved signal processing. Even on large jets with large dishes. With the lower power came more managable attenuation affects in rain too.

You do not want your head one foot away from my radar when it is on. And I wouln't let you try it, even if you asked.

Owen, I have done some tentative modelling of the CW; how valid the model is, I am not sure. I used the "TL" card for the actual coaxial feedline, and ran a single wire from the antenna feed point to one side of the TL source segment. The idea was to replicate the coaxial surface current. I don't think the balun (Isolator) will have any effect on the antenna performance. I may even have the code saved someplace if anybody is interested. Why would you not use a calibrated EMC monopole for HF?

Thanks Frank. Some thoughts...

I think they call the thing at the top a matching unit, and it seems to be a 4:1 transformer, but I have no idea of its common mode impedance that is relevant to the model.

Similarly the common mode impedance of the lower unit (Isolator) is relevant to the model, and of course the treatment of the main feedline (routing, where it is earthed).

The loss in the vertical coax is probably relevant, and not adequately modelled in NEC.

The loss in the main feedline and ATU are also relevant, and can be calculated from the feedpoint Z.

If I were building a model, I would be thinking of the assymetric dipole with the generator at the "upper" feedpoint, a vertical wire to ground loaded where the matching unit and isolator are located, and loaded for an underground coax feed (as is the case in this installation).

But, the model will depend heavily on the common mode impedance of the two proprietary boxes. Unless someone has measured these, or calibrated a model, the model results will be of limited value.

Perhaps Roy will comment on the above.

Concord Police Department Officer Ron Turner is a fucken dirty black
pig cop
he stoped me because i had 820lbs. in a 1 ton pu truck
First the cop called for chp portable scale to get the
wt of my truck he could not get one then he had me
go to the chp truck scale on the hwy to get the wt of
my truck no one was there then he had me go to moving co.
and had me drive on there scale to get wt of my truck with
me in it . the scale said i was under 6000lbs. but he gave
me a ticket for overloaded tire load range . he added the
gross wt 6000lbs + 3042 tire load range for ea tire = 12168lbs
is 18168 - 6000 - 6000 = 12168lbs ticket said i was 12168lbs
over loaded. i had me 150lbs + 2 boxes 820lbs. in bed -in the
boxes was cardboard. just before he let me go he had me go
into the restroom at the moving co. and told me to strip with 2
back up cops 1 male cop and 1 girl cop. and then he let me
go after 8 hours. got to court i showed him how to do the
math on the tire load range and he walks up to the judge and
says ALL CHARGES DROPPED.

Ron tuner who is 300lb black dirty pig cop needs to go
hunting with dick cheney .

Toilets
Police employees in Concord, California, filed a $30 million
lawsuit against the Concord Police Department after they found
a hidden in the restroom.

Wasting 60 ft of line is cheaper than a cherry picker rental, or broken leg.
I will usually tie the rope off by putting a couple of large nails within
step-ladder distance from the ground - but higher than a kid can normally
reach. Then if you need to lower it again, it may be possible.

Problem I had was getting the center conductor of 50 Ohm coax to go into the hole at the back of the 75 Ohm pin. I think they mate OK, because the skinny part of the pin has the samo OD.

Since the pin of the male connector is wholly inserted into the socket, its
diameter should not matter. The OD of the *female* center conductor should
be different. Also, the OD of the back end of the male connector (the part
that does not insert) should be different. There were dimensions available
at the Tyco web site.

The .scr is usually the screen saver program extentions. They are exicutable programs just like the .exe programs. They can take over the computer and do almost anything. Good way to pass on a virus or worm or anything if the programmer does not want to really use them as a screen saver.

> Thanks - Dan

Dan, I have done some minor approximations with your coil. I took the length and diameter to be 12", rather than 300 mm (11.8"). The coil copper pipe diameter is, as specified, 5/16" (0.3125"). I was a little confused with your use of the term "Pitch" as 0.5". In the sense of a screw thread pitch is the distance between adjacent thread peaks, but I took it to mean the actual distance between the outer walls of the pipe; in which case the actual pitch is 0.8125". If this is the case the total pipe length is just over 47 ft. The inductance calculates to 54.2uH, and the Q = 2990. I have not yet run the program in NEC 4, for greater accuracy, since I would like to get the model as close as possible in NEC 2.

If I have gotten the pitch definition wrong then the model dimensions will violate the NEC criteria of the minimum distance between adjacent turns.

The code for this preliminary run is shown below. Some of the odd-ball dimensions are just to approximately equalize segment lengths.

Despite some of the weirdness of 4nec2, concerning "GH" cards, you should be able to run it.

Frank

Source record: 63836

Roy, your analogy of the car body as a tin can really got me to thinking.

With the whip mounted dead center on the top of the car, I can see how the roof acts like a ground plane (a very short one) but I'm puzzled about the radiation from the lower part of the car body. If one visualizes RF flowing through the sides, hood and trunk of the car, the currents will all be in phase with each other (roughly, of course) but the currents are displaced in space by several feet.

How does this affect the net radiation from the car body as a whole? Is there some addition or subtraction due to having the same current, same phase but at a different location in space, and arranged in a more or less 360 degree pattern?

An interesting thought.

Frank,

Thank you. Your assumptions were correct. The only difference is 54 uH vs 75.

The model below runs on nec2. I tried a quick load it into 4nec2 without success, it seems to be confused by the GH and GS cards. I will have to pick this up tomorrow.

Thanks again - Dan

1978. Re: Question for Roy (was Re: 80m mobile antenna question)

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-04 06:31:49 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <120id2o6n2b1od9@corp.supernews.com>
Source record: 63840

Think for a moment about a wire carrying RF current. RF current in any good conductor stays very close to the surface, so it's valid to imagine it flowing right on the surface. On a wire, the current spreads uniformly around the wire (unless it's very close to some other conductor), and each little part radiates. But at any distant point, the fields from the currents at various places around the wire (at a single location along the wire) are virtually the same, so it acts like a single current filament flowing on an infinitesimally thin wire. This is, in fact, how NEC and similar programs model conductor currents.

The same even spreading happens as the wire gets fatter and fatter, but only up to a point. The model of a single current filament begins breaking down when the fields from different places around the wire are noticeably different at a distant point. This happens when the wire diameter becomes an appreciable fraction of a wavelength. Other things happen, then, too -- circumferential currents -- ones flowing around the wire -- develop, resulting in (or being caused by, depending on your point of view) non-uniform current distribution around the wire. And the wire itself affects the field. That is, the current on the side away from a distant point can't directly radiate to the distant point because the wire is in the way. Because the various current contributions around the wire won't all add together at a distant point any longer, the pattern changes.

I can't give any more specific answer to the question, really, than that the pattern will become more complex. In the case of the example I gave earlier with the cylindrical "car", if you raise the frequency, you'll reach a point where these effects happen. One result will be that the horizontal pattern will no longer be omnidirectional, but develop lobes. The height of the cylinder or car might affect the way current is distributed around it -- I haven't thought about it enough to hazard a guess.

The good news is that today's modeling programs do a good job of showing these effects. The general technique is to represent flat surfaces such as a car top or side as a wire grid, to stay within the program's requirements that wire diameter must be no more than a very small fraction of a wavelength. As long as the holes in the grid are kept to a tenth of a wavelength or less, results are quite good.

Roy Lewallen, W7EL

>is why this dimension is not critical, it is an electrical path that should be subtracted from both elements, right?
>Is it correct to shorten both elements by 1/2 of the dimension between the elements?

Harbin,

By "critical" I meant that the dimension shown can vary somewhat with
no loss of performance. For example, if you do the math you'll see
that the distance (shown in Figure 5) between the center 3/4-wave
element and the shorter 1/4-wave elements is 3.889 inches. If that
figure varied say between 3.5 and 4-inches there would be no
noticeable effect on operation. The important thing is (as I stated in
the article) is to maintain equal spacing the between the center
element and each of the outer 1/4-wave elements. The equal spacing is
the critical thing. What little change there might result in the
resonate frequency can easily be adjusted as stated in the article.

Hello,

I have owned the book for about 15 years and now I am hearing aout
errors. does anyone have a list of them?

> Thanks again - Dan

No problem Dan, I find all this very interesting. You could change all the dimensions to metric, and drop the GS card. I don't know why it is having trouble with GH. If you run some of the inductance programs, such as: http://www.captain.at/electronics/coils/, where I have used the number of turns as 14.7, and length and diameter 12"; the inductance calculates to 44.71 uH.

Minimizing the proximity effect, with #18 AWG, NEC computes z = 3.3 + j1274. Therefore Q = 433, and L = 60.8 uH; an even greater difference that the inductance programs, but closer to your requirement of 75 uH. I have tried to run the program on NEC 4.1 to see if it agrees with NEC 2, but am having trouble with connecting the helix since the end points don't appear to be in the correct position.

Jules, you really need to go back to Radar School and try and understand
the technology that your using. 7.6Kw Pulsed Xband Radars have an AVERAGE

Power of less than 20 watts. It isn't the Peak Pulse Power that fries you, or causes the sparks, it is the AVERAGE Power, and less than 20 watts one foot in front of ANY antenna is considerably less than that, due to RF Radiation being subject to the Inverse Square Law. Most of the old Decca 20Kw Commercial Marine Radars in xBand had Average Powers less that 35 watts, and were well below maximum Radiation Power Densities directly in from of the 6ft Slotline Antennas.
Your socalled Flat Dish antennas at nothing more than a tuned Phase Array, and again, one foot out in front, Power Densities are well below maximum permissable Power Densities.

Third Generation Commercial xBand Radar Technology, that came in the 80's, introduced Solid State LNA's, Ring Circulating Isolators, and Logrythemic IF ampilfiers, which improved the receivers Noise Figures, and Dynamic Gain by an Order of Magnitude. This is all in the RF Path, and had nothing to do with signal processing of baseband signals which didn't come into play untill DSP Processors were intoduced in the mid 90's and the Fourth Generation of Commercial Radars.

Manuals are written by folks who understand the technology, about as much as the lawyers, that approve them before they are published. Yes, there are safety concerns with radar operations around FBO Fueling Operations, but the incidents of actual causal problems, are rare to the extreme.

Again, all the above is TRUE only for commercial radars, and may, or may not be TRUE, and likely NOT TRUE for Military Radars, as these are more often than not CW operating, and, or doppler type radars that are NOT Pulsed.

Well, for your information, Moron, you DO NOT add the tire load range to the gross weight. The gross weight is the absolute maximum that the vehicle is designed for. The tire load range is the weight that the tire is designed to carry and have a margin for safety. The one ton pickup's maximum gross weight would be the EMPTY weight of the vehicle plus the 2000 pound weight of the cargo. face it, you screwed up. It's YOUR fault that you got a ticket, not the cops. YOU are the fat dumbass that earned it. Grow up, whiner.

I know it works in pulses and it is the pulse you should look out for.
Like a microwave oven , it can induce voltages in pieces of metal, high
enough to cause sparks. What would that do to a person with a pacemaker?

I only know the power rating.
I am not sure arcing incidents are that rare as I have met a couple of
people who claim to have seen it happen.

If a hammer drops on your foot and then rests there for 20 minutes, is
it the pulse or the average force to look out for.

My radar...

Peak Power Output: 7.5 KW nominal, 6.0 KW minimum

Output Frequency: 9375 Mhz (X-Band)

I think it does 160 pulses per second.

You would be willing to take the full brunt of that one foot away? I
will be back at the airport this afternoon and ask for someone to hold
thier head up to the radome. I never went to radar school.

I'll take your word for it, but I won't volunteer!

As an ex-RAF radar technician, during WW2 I have stood in the radar beam, on many occasions, on the airfield runway and in the maintenance workshop, just a few feet from the parabolic dish, of a 50 KW, 3 Gigahertz, airborne radar.

It was the radar which guided death-dealing machines to their targets, the many incinerated German cities culminating in the innocent city of Dresden - entirely destroyed just to educate the Russians whose tanks were only a few hours away.

I was not warned of the possible dangers of such exposure. The powers that be were not aware of them either in those days.

I am now in my 81st year. Still alive. I have fathered 5 healthy children and have grandchildren. Draw your own conclusions about the real dangers of electromagnetic radiation.

Ok sofar....

I want to receive low frequencies < 500 Khz.
Planning to build long wire for it inside the house.

How to connect this longwire to coax?

Only for receiving, do I need balun then also ?

You don't need a balun or coax.

A feedline at low frequencies is very much short of a wavelength.

Just extend your antenna wire direct to the receiver. Perhaps use a
tuned preselector. And away you go!

I'm not lucky. I'm just an ordinary person. My genetic history
remains unaffected by high-power electromagnetic radiation. On the
contrary, it seems to have done me good!

But if I should eventually die with a brain tumour no doubt my
electromagnetic history will unjustly be blamed. ;o)

Nobody's books or publications are bibles.\
What are we supposed to believe? It would take many years to verify
all that has been printed over the last 100 years. If I am a ham and I
wish to put up an antenna, what should I do? Surely not refer to to
the Bibles.

Incidentally, in 1945, I was an unsuspecting guinea pig sent to the radioactive aftermath of Hiroshima for a week or so.

Again, my genetic history appears to have remained unaffected. Perhaps, as you say, I am lucky.

I am just another very minor statistic, like everybody else, in the field of statistics and probability. See the widespread works of Sir Ronald Arthur Fisher, the greatest statistician of all time who died in the 1960's. Just imagine what he could have done with just a modern pocket calculator, never mind a personal computer.

==========

Nobody understands the bibles without a great deal of study. They are full of mistakes anyway. Most of them were written just to make a living. Its easy to understand what THAT leads to.

Just put up some wire and you will learn more in a few hours of listening and transmitting than a lifetime of reading about it.

Before throwing stones like that, you might consider applying the concepts
of punctuation and capitalization to your posts. It may take a little of
the second grade charm out your writing, but it will certainly make you seem
to be much less of a fat dumbass yourself.

I fully admit my antenna programs are not bibles.

They are merely my idea of how things can be modelled.

In general they are well inside the ball park.

They serve their intended purpose.

What better quality can you ask for?

I am a Fellow of the British Institute of Quality Asurance but I don't
brag about it.

Well, your whiney blathering is rather difficult to read. You haven't figured out where the Shift key is or what it's for and your writing is atrocious. If he had you weighed the scales would have told him that you were not overloaded, if you were loaded as you claim. Personally I think you are just a whiney moron who got a ticket and can't deal with it. Now please stop cross posting to AFPF. Cross posting is not welcome there.

An interesting point of view. I have been participating in a Bible Study program for the last three years based on the Old Testament and the New Testament. One of the more important things I have learned is that there are many inconsistencies and cases of ambiguity.

We are fortunate in all cases that someone was willing to sit down and put the documents together so that we could enjoy the benefits of their studies!

If Terman made an error, I can forgive him. My copy is older than I am...

Sometimes a published error is what it takes to get the right answer.

BTW, thanks for all the programs Reg. I am learning a lot from them!

Source record: 63866

I have just had several glasses of Australian Zonte's Footstep wine.
I can recommend it. Its name can be traced back to a marsupial which
replaced the dinosaurs.

Transmission lines, which even the dinosaurs knew nothing about, are
associated with losses of one sort and another. But there is one sort
of loss which is never mentioned in discussions on this newsgroup. It
is reflection loss.

Reflection loss is sometimes known as mismatch loss.

It is that loss which occurs in the load impedance because it is not
matched to the line impedance Zo. When the line is not matched there
is a reflection of amps and volts back towards the generator.

The reflected volts and amps, in conjunction with the existing volts
and amps, present to the generator an impedance which causes it to
deliver to the line exactly the power in the load plus the power lost
in the line. That this occurs is quite obvious.

When calculated, the power lost in the line automatically takes into
account the increase in loss due to SWR which occurs on the line due
to the mismatch of the load.

But the most important parameter is not the SWR but the reflection
coefficient, Gamma.

Gamma = (Zt - Zo) / (Zt + Zo).

The loss in the load due to reflection is given by

Reflection Loss = 4.343 * Ln(1 - Square(G)) decibels.

where G is the magnitude of the reflection coefficient which is easy
to measure.

Reg.

A tuner will present the designed-for impedance to the
generator and thus develops reflection gain that neutralizes,
to varying degrees, the reflection loss at the load.

Ah, yes!

I have been a Californian most of my life (now 63+). Our cops rarely seem to care what you have in the back of a pickup. It would have to be a cage full of naked, screaming children to get their attention. They want the speeders, the weavers, the red-light runners -- all genuine hazards.

In fact, overloaded pickups are quite common -- with tall sideboards to contain all the junk -- yet I can't remember the last time I saw one pulled over.

I have checked with the local shipping service.

Shipping via FEDX will be between $150 and $200 to most address on the US mainland.

I have seen Marauders not meet the reserve on Ebay at over $150 plus shipping.

I will sell this one for $100 plus the actual shipping cost charged by the local shipping store.

Source record: 63871

I needed an indoor HF antenna recently and had a 40 ft roll of Radio Shack twinlead. I cut down the middle about 16.5 feet, hung one end at one side of the room and the other end at the other side of the room and fed it into the balanced line input on my tuner. It tunes easily. I have no ground set up, so I ran another 16.5 foot wire from the ground port. Making contacts is a bit of a struggle, from my QTH in Michigan I've worked Nevada and Arizona on PSK and during the DX contest today in limited operation near sunset I worked Barbados and the Dominican Republic with about 50W (probably a bit of a high level of RF radiation, I know). The question I have is what the downside of this is. I have seen many websites that show various antennas fed with twinlead, but I've never seen my approach (the twinlead used for both the antenna and feedline). Since I got this roll of twinlead on clearance from Radio Shack for 38 cents, this is a cheap antenna indeed.

Following quote is lifted from Symantec [Norton Antivirus], edited only for
brevity:

< quote>
Symantec Security Response encourages all users and administrators to adhere
to the following basic security "best practices":

* Configure your email server to block or remove email that contains
file attachments that are commonly used to spread viruses, such as .vbs,
.bat, .exe, .pif and .scr files.
<end quote>

If you wonder what you're missing in scr files, you could be a mite too
curious.

I'm going to suggest you "waste" not only the sixty feet of rope at each
end, but an additional sixty feet at each end. (But, not being acquainted
with sycamore trees, I don't know how dense their branches are, so
this idea may not always work.)

Create a closed loop of rope, so you can raise and lower the thing at
will with total, personal control. You will someday need to lower
the antenna and growth in the tree may snag the insulator or the
antenna, so you could tug down on a rope, and not have to tug down
on your antenna.

I am curious about the pulley. Hereabouts (Southern California) we
do almost nothing with trees.

John

Paul,
Should work fine on the higher frequencies. But it may have limited utility
on 160, 80, and 40
since it is only about 10 meters long. I assume your contacts were on 20
meters. where your
balanced line might be near 72 ohms.

If it is truly balanced you should not need a ground. Assuming
that the high RF in your room does not bother your rig/setup and assuming
that no one gets burned
by coming in contact with the antenna while you are operating, you should be
ok.

Balanis illustrates exactly that idea on page 18 of
"Antenna Theory, Analysis and Design", 2nd edition.
It is a very old idea. 50+ years ago, when I was a
Novice, it was standard practice to tie a knot in zip
cord 1/4WL from the end, unzip the cord down to the
knot, use the unzipped part for the 1/2WL antenna,
and use the rest for balanced feedline. It worked
like a charm in spite of the feedline losses.

Indeed, Reg.
It's always struck me as rather annoying that there are more errors in books on electronics than in any other published subject _bar none_ to my knowledge. I can think of no text book that is entirely error-free with the _possible_ exception of Art of Electronics.
Most of the errors in radio & electronics tomes are related to ambiguous authoring, but there is a regrettably large number of outright errors (examples calculations or fundamental misunderstanding on the part of the writer) that are utterly poisonous snake oil to the unwitting and unguided student. Chris Bowick's 'RF Circuit Design' springs to mind here!

Maybe. But I dare say his English is a darn sight better than yours!

2020. Current in Loading Coils

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-05 15:01:15 UTC
From: Cecil Moore <mycall@arrl.net>
Message-ID: <%2DOf.39694$F_3.36050@newssvr29.news.prodigy.net>
Source record: 63730

A loading coil thread is climaxing over on qrz.com. I have used EZNEC to generate a graphic which shows a 3/4WL vertical and a similar 1/2WL vertical with a ~1/4WL loading coil. The loading coil is a wire helical coil containing (surprise) roughly 1/4WL of wire. The coil does a good (not perfect) job of replacing 1/4WL of wire. Many things can be gathered from observation of the current reported by EZNEC for the two antennas. The coil occupies roughly the same number of degrees of the antenna as the wire it replaces. The current at the top and bottom of the coil is roughly the same as the current at the two ends of the wire it replaces. Is the coil an exact replacement? Of course not.

EZNEC says the current flowing into the bottom of the coil is 0.1168 amps and the current flowing out of the top of the coil is 0.748 amps. Say what? How can more current flow out of a coil than is flowing in? Aren't those two currents supposed to be equal? What gives?

Some gurus have mistakenly treated the net current on a standing wave antenna as a lumped circuit current. The lumped circuit analysis falls apart in the presence of standing waves and the myth of equal net current in and out of a coil has been created as a result. Hint: A typical mobile antenna is a standing wave antenna and the net standing wave current reported by EZNEC doesn't much flow at all. It just, well, stands there like good little standing waves are supposed to. That standing wave pattern is illustrated in the graphic at:

http://www.qsl.net/w5dxp/qrzgif35.gif

The two EZNEC files used to generate that graphic are available from me upon request.

Just got an email that prompted me to expand this statement.
The worst thing about replacing a piece of wire antenna with
a coil is of course, the wire radiates well and the coil
radiates hardly at all. But that's a compromise we are forced
to live with for 75m mobile antennas.

> enough to cause sparks. What would that do to a person with a pacemaker?

No, absolutly NOT, Microwave Ovens are NOT pusled, they are CW, and
continious. It is AVERAGE Power that fries you, not Peak Pulse Power.
See, this is what you seem not to understand, about the technology that
is being discussed. You don't seem to have a grasp of how the technolgy
works.

>
> I only know the power rating.
> I am not sure arcing incidents are that rare as I have met a couple of

> it the pulse or the average force to look out for.

not analogous, at all, and just shows that yoiu don't undertand the
technology that you talking about.

>
> My radar...
>
> Peak Power Output: 7.5 KW nominal, 6.0 KW minimum
>
> Output Frequency: 9375 Mhz (X-Band)

Most likely using a 2J42 Magnitron or equivilent....

>
> I think it does 160 pulses per second.

that seems a bit low, should be in the 500 to 750 range, but ok..

and the Pulse Width, which you don't cite, is the determining factor
in calculating the Average Power of the RF Energy emitted from the

device. Typical Pulse Widths would be in the .1 to 1 microsecond range
for this type of radar. So lets take 1 microsecond.
1 * 160 = 160 microseconds total ON time out of 1000000 microsends/second
160.0/1000000 *7500 Watts Peak Pulse Power = 1.2 Watts Average Power

Now understand that RF Energy is nonIonizing radiation and therefore
interacts with biologics as HEAT. Now just how much heat will be
transfered to you from a 1.2 Watt light bulb held in your hand,
assuming that you get 100% capture of that power into your hand,
and considering that if your standing out in front of the antenna
even at one foot, the Inverse Square Law still applies?

>
>
>

2032. Current through coils

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-05 19:47:28 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <duff8gear1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 63743

Different currents at each end of a coil are easily explained.

A coil has capacitance to its surroundings distributed along its length. And current flows from it radially.

Every coil has length. Both L and C are distributed. Therefore the coil behaves as a transmission line. There are standing waves. Current and voltage both vary with length.

The longer the line the greater the variation.

The line has phase-shift, Zo and attenuation resulting from wire loss resistance and radiation resistance.

The line can have a resonant length. It then becomes a short antenna.

The whole business can be mathematically modelled.

Reg, G4FGQ.

Reg Edwards wrote:
> The whole business can be mathematically modelled.

The point is that it cannot successfully be modeled
with the lumped circuit model where the current is
constant everywhere in the circuit. What would
Kirchhoff have thought about a coil with 0.1 amp
at the bottom and 0.7 amps at the top? It certainly
doesn't mean that 0.6 amps is flowing sideways. All
it means is that the relative phase of the forward
current and reflected current changes through the
coil and therefore the distributed network model
needs to be used.

2035. measuring impedance through a balun ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-05 20:04:46 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <hLedncOeu6382ZbZnZ2dnUVZ_sOdnZ2d@comcast.com>
Source record: 63746

All,

I am trying to measure impedance through a balun, or more accurately a 1:1 in line "transformer". For test purposes the transformer is two windings of 10 turns each on a toroid. The winding are tightly wound on opposite sides. The material is #43, the toroid is 3/4 inch OD.

If I drive one side of the transformer with one milliwatt at 4 MHz and terminate the other side into 50 Ohms, and then measure the input voltage and the output voltage. The output voltage significantly less then the input voltage, about 1/3.

The second measurement that does not support my understanding is: If I connect the transformer up to an 8450A through appropriate couplers, and then short the output the 8405A does not show a 180 degree phase shift between 'open' and 'shorted'. If this measurement is made without the transformer then the results are as expected.

This is obviously something with the transformer. I would like to construct a simple 1:1 in line transformer good from 3 to 30 MHz and 100 watts. What core size, material, and windings are a good starting point for this?

Thanks - Dan - kb0qil

For 4 MHz, I would use #61 material and
bifilar windings.

>the coil is 0.748 amps. Say what? How can more current
>flow out of a coil than is flowing in? Aren't those two
>currents supposed to be equal? What gives?

I thought the power was constant, not the current. If that is the case, then IE must be constant and therefore the current must go up where the volts go down.

I would appreciate the EZNEC copies because I learn easiest by examples and I am interested in how you put the comparison together.

Dan, I think #43 is powdered iron, which is fine for high Q inductors, but not very good for broadband transformers. As has been mentioned by others; a ferrite core with bifilar windings should do it. Check out: http://www.oselectronics.com/downloads/Broadband%20Transformers.pdf for more info.

2041. Compact loop question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-05 22:41:54 UTC
From: "John, N9JG" <john@gotwals.XremoveY.com>
Message-ID: <SOJOf.803471$x96.268170@attbi_s72>
Source record: 63752

I am in the process of constructing a compact loop for 80 meters. The loop is constructed from 3/4 inch copper pipe in the shape of an octagon with a perimeter of 72 feet, and the plane of the loop is vertical. According to the literature, a loop of this type usually has a remotely tuned capacitor in series with the top side of the loop, and the loop is feed at the bottom with a gamma match.

For mechanical stability reasons, I would like to have the tuning capacitor at the bottom of the loop, and feed the loop at the top of the loop. The coax would be constrained to lie in the plane of the loop and would drop vertically from the top of the loop to the ground. What disadvantages, if any, are there to this second method of loop construction?

For more details of my project, see http://tinyurl.com/bwobb

Hi John,

What advantage is there in climbing a ladder to place the loop? Put
it at the bottom too.

Type 43 is a nickel zinc ferrite. Spec sheets indicate it is
principally a suppression material, but usable for broadband
transformers up to 10MHz.

Bifilar winding, and possibly better material are probably the key to
improving the transformer, or alternatively making a common mode
choke.

2047. Vertical vs Horizontal shootout part one

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-06 00:29:12 UTC
From: Mike Coslo <mremovethiscoslo@adelphia.net>
Message-ID: <c4-dnXFHg8_KH5bZnZ2dnUVZ_vmdnZ2d@adelphia.com>
Source record: 63758

Based on another thread a few weeks back in which Horizontal dipoles were being compared to Vertical antennas, and from a little chiding from Roy, W7EL, I decided to do some testing on my own personal versions of the two.

My setup is:

Icom IC-761
Antenna 1 - Homebrew OCF dipole at ~ 50 feet.
Antenna 2 - Butternut HF6V -ground mounted and 18 radials on the ground.

Part one of this experiment is to calibrate the S-meter. I found that trying to calibrate the thing with on-air signals was a nuisance, and probably wouldn't be as accurate, so I used a signal generator.

I started out with a +20 signal, then worked my way down.

+20 start
S9 -18 db
S8 -23 db
S7 -26 db
S6 -29 db
S5 -32 db
S4 -35 db
S3 -37 db
S2 -39 db
S1 -41 db

All in all, I would have to say that the meter tracks very well from S8 to S4, and the only place that wasn't that great was from S9 to S8. But considering the transient nature of the signals we are receiving, I would have to day that the S-meter is of reasonably close accuracy.

With my newly calibrated S-meter I am ready to start looking at what the two different antennas are doing for me. I have a coaxial switch to jump back and forth between the two. My initial impressions are that there are some surprises. The difference in noise levels varies by antenna by band. On some bands the vertical is noisier, and on others it is the OCF dipole. Especially intriguing is that on PSK mode, where I can see several signals at one time, switching between antennas will attenuate some signals, while other signals increase in strength. I think that my vertical works better than I gave it credit for, but If I definitely want *both* antennas.

Next installment will be the band to band comparison of the two antennas with some numbers.

Installment three will be an investigation of that PSK signal strength business.

Question, does the magnitude of feedline radiation from the OCF
(presumably predominantly vertical) significantly affect qualification
of it as a horizontal antenna?

Another, are the antennas coupled significantly, eg is one within the
near field zone of the other? It is pretty hard to avoid in a
residential block on the low bands, and it will confuse the results
somewhat.

Not only is the shape of the scale an issue, but the granularity or resolution, especially with LCD meters, or any meter where there are discrete steps in the meter current (such as where a D/A converter drives the meter movement).

If you want to move beyond S meters, you could try FSM (www.vk1od.net/fsm) and organise some constant carriers at known distances / radiation angles that you could make a series of measurements of and produce summary statistics (median and inter quartile range) for each antenna type.

I described a technique for assessing the relative performance of mobile stations by having them transmit known constant carrier, each station space about 200Hz and turning circles in a carpark near each other, and to observe them at typical propagation distances with an audio spectrum analyser, watching the relative strength of the carriers.

Your PSK setup is affording you the same type of comparison, and provides a ready (and recordable) assessment of the relative strength of the stations under the two antenna scenarios. Be great if you could orchestrate stations at known distances as part of an organised test.

Cecil,

Interesting.

I am quite familiar with Kirchoff's equation in regard to voltages around a loop and his equation about currents at a node. Did I miss a third equation regarding currents around a loop?

Hint: Kirchoff would not be the slightest bit bothered by this problem.

Reg, as usual, has it completely correct.

Nope, you missed an implication of Kirchhoff's current law.
Unequal currents into and out of a passive black box implies
the existence of a node inside the box.

Wow! It is really great when something simple works. Yes, 6 bifilar windings work really great. Even better the impedance measurements worked as expected.

Now I need to design 2:1 and 4:1 impedance matching transformers for 500 watts. Those are in anticipation of successfully resolving the ground of the antenna system.

Thanks - Dan

Cecil,

Your response makes no sense at all. Unequal currents into and out of a passive black box implies charge storage, which generally means capacitance.

You cannot have it any other way, with or without waves or reflections. Conservation of charge is one of the most fundamental laws in nature.

Reg was correct.

Time for my Bow and arrow story....

A few years back I decided to do the antenna thing with a bow and arrow. I didn't have any dummy heads, so I took the head off of a practice arrow and wrapped a wad of duct tape around it. I attached a string to the rear of the arrow. The kid saw me leaving the garage with the bow, and decided to tag along. You never know when the Old Man is going to do something funny. As he puts it, "for such a geeky hobby, there are a lot of funny outside moments". We set up under the trees, and started.

The first couple of attempts were pretty lame, with the arrow only going up about 20 feet or so. So I pulled back a good bit more......

Let me tell you, compound bows have more or less two speeds that they impart to the arrow - almost nothing, and holy crap! The arrow heads off, goes waaaayy above the treetops which are around 100 feet in my yard, reaches the end of the string, breaks it, and then continues up a bit more - I guess - because I lost sight of it. I heard something go "thump some where.

It was getting kinda dark at this point, but I wanted to see if we could find it. The neighbors put up with most of my quirks, but I don't think they would appreciate arrows landing in their yard. So the kid and I hopped in the car and drove around the neighborhood a few times. Didn't find the arrow. I felt pretty dum by this time. A few weeks later, the lad found the arrow only about 30 feet from where I had launched it. Go figure. Thank heavens it didn't knock out any of the neighborhood dogs.....

I now use a fishing reel/slingshot launcher. After a while, you can get pretty good with them. About half the time I can get it around the right limb on the first try.

> I can't figure a way to hoist all this up without, say, 120 feet of

> the antenna. Yes, I can use a slip knot but I still end up having 60
> feet of rope draped from the tree. Should I find a way to cut the nylon
> rope near the branch? Just tie up the hanging rope?

Here is what I do. I use nylon rope of the sort used for chalkline. It is very strong, and will stretch nicely if the trees head in the opposite directions in the wind, but will spring back. Be careful that you don't get the poly type - that stuff is nowhere near as strong.

After shooting the weighted line over the desired limb, I tie the nylon line to it, and haul it back. I then attach that line to the antenna end (be sure you nave an insulator on it. Then pull it through. I then leave enough line so that I can pull back through. I have attached one of those horn shaped pieces of metal such as is used for tying off flag lines on a flagpole. Then I simply wrap the line around it. Don't worry about the "waste" because it really isn't waste. How else ya gonna do it?

> It seems necessary to "waste" as much as 60 feet of rope in either side.
> If I support the center insulator, then double that.

Unless the antenna is extremely heavy, the nylon string method I use will hold that antenna pretty straight. I'm using an OCF dipole, and it even has a balun in the middle.

> Is there a better way?

I personally wouldn't bother with pulleys on tree antennas. Something seems to happen that necessitates putting a new (name the part) for that wire antenna fairly often anyhow.

I'm glad to see that my chiding has had a positive result.

Be sure you calibrate your S-meter on each band you'll be using it on, and that the RF gain control and any preamplifier and input attenuator settings are the same as they are when making measurements.

Especially when comparing horizontal and vertical antennas, you'll likely have to make several measurements over a period of time. I've seen many cases where one antenna is a good 20 dB stronger than the other, then over the next minute or so their relative strengths reverse. This is due to polarization rotation of the received signal. On 40 and 80 meters at least, this is common and often has a period of around a minute or more. Really makes me chuckle when I hear "Ok, this is antenna 1. Now this is antenna 2. Which is stronger?"

If neither antenna is consistently stronger than the other, you can put a fixed attenuator is line with one of the antennas and the step attenuator in line with the other to make comparison easier.

People who blindly assume the marks on their S-meters are 6 dB apart should take a good look at your calibration results.

Hey, good one! Nice laugh, here.

I'm not one of "Them," however. I believe that trees are a crop, like so
many
useful plants. I mean, you never hear protesters wailing, "Save the lima
beans."

Now, I think I'll go put an antenna up in a tree -- just to do it.

73,
John

Anyone that was involved with the Nike Hercules missile system in the late Fifties and through the early Seventies was around high powered pulse radar. It was deployed around major metropolitan areas in the States and other places around the globe.

All the tracking stuff was short pulse "X" band and maybe a couple hundred watts average.

But the big stuff was the acquistion or search radar that was "L" band. The one I worked with in Korea was maybe 5 or 6 megawatts peak and 4 or 5 kw average on the "L" band.

Some Stateside sites had the big G.E. "L" band job that was fairly long pulse and put out 10 megawatts peak and 18-20 kw average. I was real pleased that it had a rack mounted Bird wattmeter and I was impressed to see a solid 18-20 kw average power running through the waveguide to the antenna.

The range radar was Ku band (15-17 kmc) (TRR to you Nike guys) and one of the old timers I worked with told me that if you directed the antenna towards an individual, he would feel the heat. And I'm sure that's true. We're all familiar with microwave cooking.

Reg, G4FGQ wrote:
"The most important parameter is not SWR but the reflection coefficient, Gamma."

My age is about the same as Reg`s. I have 4 children and 6 grandchildren, and am a veteran of WW-2, but doubt that adds to my credibility. Neither does the beer I had with dinner add authority to what I write. I have a degree in Electrical Engineering, but Americans and probably Brits too view this credential with suspicion. It did open the door to good jobs.

Reg expresses disdain for "bibles" such as Terman or Kraus but their writings have endured the test of time and are proved by countless experiments.

On page 99 of Terman`s 1955 edition of "Electronic and Radio Engineering" (my textbook was an earlier edition) is found the formula to convert the reflection coefficient into SWR or vice versa. These two parameters are innexorably locked together by formulas (4-22a) and (4-22b).

There really is no need to rename the ubiquituos SWR meter as Reg has recommended. This really requires no comment as it isn`t about to happen.

Best regards, Richard Harrison, KB5WZI

Now explain how you'd do it with a box having only two terminals -- and assuming the box is very small compared to a wavelength.

Richard, formula 4-22b calculates the magnitude of the reflection coefficient from SWR. It is not possible to calculate the reflection coefficient (as you say) in the general sense since you lack the phase information.

Owen Duffy wrote:
"Richard, formula 4-22b calculates the magnitude of the reflection coefficient from SWR, it is not possible to calculate the reflection coefficient (as you say) in the general case since you lack phase information."

Phase information is not needed. It is true that the reflection coefficient is a vector ratio of the reflected voltage to the incident voltage at the load but this does not affect conversion of the reflection coefficient to the SWR.

Reactance at the load has the same effect as adding a same-impedance line (of particular length) between the generator and load. This only shifts the SWR pattern on the line, but in a practical line has no effect on the minima and maxima on the line.

SWR is simply the ratio of the maximmum amplitude to the minimum amplitude of voltage (or current) on the line in a particular region of the line. A maximum is displaced by 1/4-wave from a minimum.

Phase information is irrelevant to conversion between reflection coefficient and SWR. That`s why Terman didn`t include it.

"Now explain how you`d do it with a box having only two terminals--"

I`ll give the mathematician`s answer: "It`s of no interest. It`s already been solved." Cecil said he would put a coil in the box. I agree. Retardation between incident and reflected waves in each direction would in most cases cause a current difference between the two ends of the coil. Unlike the usual transmission line, the wire is coiled to get reactance into a small space. The effect is the same in that phase shift is distributed along the length of the wire. There is just more of it and and the intervals between maxima and minima are short. Impedance and therefore voltage along the vire is a function of site along the wire. There will be a standing wave pattern throughout the coil.

==========

Richard, I'm afraid your worship of Terman has let you down.

The two parameters are NOT inexorably locked together.

SWR can be calculated from the Reflection Coefficient. But half of
the information is then lost and gone for ever.

And so, NOT vice-versa!

Reg.

Cecil,

This is getting more interesting by the moment. Have you now removed some of the well-known physical attributes of wire and transmission lines? Specifically, what happened to the L and C of the wire?

I have no issue with the use of network theory, reflection coefficients, standing waves, or any other commonly used descriptions. However, none of these mathematical conveniences change the fundamental physical laws. If current, and therefore charge, appears to be unbalanced, then there must be charge storage somewhere.

As Reg pointed out, the charge is stored in the capacitance of the coil. No need to invoke any magic incantations about networks and standing waves.

In principle any of these problems can be solved with very basic equations found in any E&M text. In practice it is extremely cumbersome to do so, and that is why all of the network formulations have been developed. Just don't fall into the trap of thinking that any new physical behavior is created by the reflections and standing waves. I believe in previous messages you have referred to that thinking as "seduced by the math models."

Yes. Dunno if I'd call it reliable though <grin>. If you had this kind
of system on a moving vehicle for example the RX would have to be able
to follow the TX. You'll get about +-200Hz shift with a speed of 100kph.
(ie 400Hz as a vehicle goes past you)

I have been intending for ages setting up a 2m beacon on my car and
seeing if I can yield any driving location/speed etc info from the shift
and phase noise. (11Hz at 100kph)

Cheers Bob VK2YQA

Assume a one-wavelength dipole off-center fed 1/4WL from
one end. Using EZNEC with 60 segments, feeding at segment
number 15 is 24.2% from one end and that's close enough
for this example. This is actually done in EZNEC with a
130 ft. dipole on 7.2 MHz and I'll email out that file
upon request. I'm going to describe the current
distribution in the following diagram with 60 segments
running from left to right in *fixed font*. Eash dash
corresponds to a segment in EZNEC and F is the feedpoint.

```
seg L L seg
1 v v 60
--------------F-----------------------------------------
^ ^ ^
N N N
```

The current distribution is sinusoidal. N stands for 'node'
which is a current minimum point. L stands for 'loop' which
is a current maximum point. Since I'm limited to ASCII, the
reader will need to imagine a current envelope drawn from
seg 1 up to 'L', down to seg 30, back up to 'L', and back
down to seg 60. I'll follow this posting up with actual
EZNEC graphics posted to my web page.

Now we are going to replace part of that wire with a 6" long
coil. A 6" long coil on 7.2 MHz is about 1/3 of one percent
of a wavelength so that should qualify as 'very small'. And,
to illustrate another fact, I'm going to make the coil from
1/4 wavelength of wire, 33' on 40m, and try to model that
using the helical coil feature of EZNEC. That may or may not
violate an EZNEC design rule - I just don't know yet. But
it doesn't change the concepts being presented here.

Let me say this is a very rough approximation to what happens
in the real world. The concepts are accurate. The values may
be off by a relatively large percentage. The coil certainly
distorts the current away from that near-perfect sinusoid and
certainly doesn't radiate like the wire it replaces. But roughly,
here will be the results of placing the bottom of the coil at
seg 30:

```
seg L L seg
1 v v 46
--------------F---------------////----------------
^ ^ ^
N N N
```

The current at the left end of the coil will be low because that is roughly the location of a current node (minimum). The current at the right end of the coil will be high because that is roughly the location of a current loop (maximum). If one considers the current flowing from left to right, more current will be flowing into the coil than is flowing out of it, like the current at:

http://www.qsl.net/w5dxp/qrzgif35.gif

This is a standing-wave antenna so the standing-wave current displayed by EZNEC is flowing hardly at all. That standing-wave current consists of two component phasors, rotating in opposite directions. That's why the phase of the standing-wave current is relatively constant. The standing-wave phasor, the superposition of the forward and reflected current phasors, rotates hardly at all, usually by just a few degrees from end to end in a 1/2WL dipole. If the dipole is made of 'thin wire', the phase of the standing-wave current is fixed at zero degrees. (Can a phasor that doesn't rotate be called a phasor?)

Taking 1/4WL of the antenna wire and winding it into a high-Q coil above replaces *roughly* 90 degrees of the antenna. The radiation pattern certainly changes because the coil doesn't radiate much. But we are not concerned about radiation patterns in this discussion. We are concerned about the current at each end of the coil, the same current that we measure and the same current reported by EZNEC. That current is certainly not constant through the coil and THE DIFFERENCE IN THE MAGNITUDE OF THE CURRENT AT EACH END OF THE COIL DEPENDS UPON WHERE IT IS PLACED IN THE STANDING-WAVE SYSTEM.

The traveling-wave current through a coil is close to equal at each end. The standing-wave current at each end of a coil is NOT equal unless we locate the center of the coil at a current node or at a current loop. In a bottom-loaded mobile antenna, the coil is located very near a current loop where the slope of the current is near zero. In fact, the net current peaks inside the bottom-loading coil.

So the concept that net current at each end of a coil installed in a standing-wave environment is equal is just a myth, an old wives' tale that needs to be banned from ham radio.

The coil does indeed cause considerable distortion away from the perfect cosine current wave exhibited by a thin wire. But the macro effects of that cosine wave still exist when a coil is

installed. The current at each end of a coil installed in a
standing-wave antenna depends upon its location in the system.

> reactance into a small space. The effect is the same in that phase shift
> is distributed along the length of the wire.

W8JI measured a 60 degree phase shift through a 100uH coil
at 1 MHz. Consider that at one end of that coil the
forward and reflected currents may be:

Ifor = 0.55 amps at zero deg, Iref = 0.45 amps at zero deg.

Inet = Ifor + Iref = 1 amp at zero degrees.

At the other end of the coil, the forward and reflected
currents may be:

Ifor = 0.55 amps at +60 deg, Iref = 0.45 amps at -60 deg

Inet = Ifor*cos(60) + Iref*cos(-60)

Inet = 0.275 + 0.225 = 0.5 amps at zero deg

Some items of note:

1. The forward current magnitude is the same at both ends
2. The forward current phase is shifted by 60 degrees
3. The reflected current magnitude is the same at both ends
4. The reflected current magnitude is shifted by -60 deg
5. The forward and reflected current phasors rotate in
opposite directions
6. The net current phase is unchanged through the coil
7. The net current magnitude is changed by 100% from 0.5
amps to 1.0 amps.

Dear Richard,

You must have a very extensive library.

By the way, it is NOT Terman or his books which I disdain.

It is the TREATMENT, by his readers, of his books as Bibles which I disdain.

The situation is on a par with the more modern, unjustifyable, absolute confidence placed in computer programs and pocket calculators by their users.

Computer programs have authors. How much confidence can be placed in THEM is what matters.

Amongst my exceedingly small collection of books is one of Terman's. It was printed during WW2. I bought it, second hand, just after the war. 60 years back I learned, critically, a lot from it. Nowadays I refer to it every few months when searching for something about which to write another computer program. So the book is still quite valuable as a comprehensible collection of topics.

I have nothing from Kraus. I know of him only from the frequency at which he is referred to by bible worshippers on this newsgroup.

I have read about B,L & E. They are the famous trio who left the site without bothering to measure ground resistivity. Their boss should have sent them back. Who was HE? He must have known what they were up to less than THEY did.

Being a WW2 veteran I'm pleased to meet you. The experience, like mine, was educational. And I'm sure you have a sense of humour similar to mine. ;o)

Regards, Reg, G4FGQ.

> If current, and therefore charge, appears to be unbalanced, then there
> must be charge storage somewhere.

Gene, the flaw is in your misunderstanding of the
fundamental physical laws, not in those laws.

We measure the net current at one end of a coil at 0.1
amp and we measure net current at the other end of the
coil at 0.7 amps (my web page example). The net current
APPEARS to be unbalanced, but appearances can be
deceiving. THERE IS NO STEADY-STATE CHARGE STORAGE
ANYWHERE IN THE SYSTEM. Does this violate any fundamental
physical laws? Of course not. Here's why (neglecting losses):

V*I*cos(theta) equals the same power at both ends of the
coil. That proves there is no steady-state energy storage.

V1*(0.7)*cos(theta1) = V2*(0.1)*cos(theta2)

This is a distributed network. A lumped circuit analysis
fails miserably when you try to use it in a standing-
wave environment and you have just proved it. That is
also the same mistake that W8JI and W7EL have been
making.

The forward current at the 0.7 amp point is 0.4 amps at
zero deg. The reflected current at the 0.7 amp point is
0.3 amps at zero degrees. The net current is the phasor
sum of those two component currents.

Inet = (0.4 amps at zero deg) + (0.3 amps at zero deg)
Inet = 0.7 amps at zero deg

The forward current at the 0.1 amp point is 0.4 amps at
82 degrees. The reflected current at the 0.1 amp point is
0.3 amps at -82 degrees. The coil causes an 82 degree
phase shift in both forward and reflected currents and
since their phasors are rotating in opposite directions,
the sign of their phase shifts are opposite.

The net current at this end of the coil is:

Inet = Ifor + Iref
Inet = (0.4 amp at 82 deg) + (0.3 amp at -82 deg)
Inet = 0.057 amps + 0.043 amps = 0.1 amp at zero deg

The fundamental physical laws are perfectly valid as has been demonstrated here. It is your understanding of them that seems to be the problem. You seem to have been fooled by appearances and as a result, you chose the wrong model with which to try to solve the problem. The distributed network analysis was developed because the lumped circuit analysis falls apart under certain circumstances. One of those circumstances is the presence of standing waves like the ones that exist in a 75m mobile antenna.

==========

Richard,

Maybe you are right about no need to rename the SWR meter. It does indeed indicate SWR when located at the correct place in the system, it is correctly calibrated impedance-wise, and there is a line on which it can be assumed an SWR exists.

But where the thing is located in 99.9 percent of occasions it indicates nonsense. Where SWR on the antenna's feedline is concerned it is totally misleading to novices, CB-ers, amateurs and professionals alike. Hardly educational!

I have noticed a few references to TLI are beginning to appear. All that's needed is a sensible Japanese, Chinese or Korean transceiver manufacturer to face the facts and refer to TLI in an operating or maintenance manual.

I know its sometimes difficult to learn a new word in a new way of thinking but force yourself to comply with the obvious!

It's much easier than having to change to the Metric System. The same economies apply.

Reg, G4FGQ.

Gene Fuller, W4SZ wrote:
"This is getting more interesting by the moment."

There are plenty of coils in boxes which have different currents into and out of their two ends.

A coil in a box used to be a common way to resonate a too-short 1/4-wave (90-degree) whip. A company I worked for had many Land Rovers, trucks, boats, and ships on and around the Argentine side of the island of Tierra del Fuego.These were equipped with H-F SSB tranceivers. Mobile amntenna was a stainless whip mounted atop a substantial fiberglass box. The box contained the loading coil which was accessible for preselecting the right coil tap to resonate the whip with the vehicle for a particular operating frequency. The box also contained a motor-driven band-switch to automatically change taps on the coil when the frequency was changed on the radio.

I am well aware of the ability to resonate a 90-degree whip with no more than the proper coil in series with the short whip on a base insulator. I tuned every one of those coils for each of the frequencies we used in Argentina with my own hands.

ON4UN has a graph, Fig 9-22 on page 9-15 of "Low-Band DX-ing" which shows current distribution of a base-loaded whip, In his example, the whip is 45-degrees long.. The loading coil provides the extra 45-degrees required for resonance.

Current at the base of ON4UN`s whip is one amp times the cosine of 45-degrees, or 0.707 amp. The loading coil has an input of one amp.

With 1 amp into the loading coil and 0.707 amp out of the loading coil, the coil definitely does not have the same current at both ends.

Best regards, Richard Harrison, KB5WZI

The calibration of S-meters, 3dB or 6dB per S-point, has nothing to do with which antenna produces the stronger received signal. It is purely a comparison. Just use the same meter throughout the tests.

Roy, you must be still be using that ancient receiver. No doubt it is working fine. But you still refer, quite arbitraliry, to your personal S-meter as the North American Calibration Standard. Must everybody else fall into line? Not me!

> the coil definitely does not have the same current at both ends.

It's not that perfect in the real world but the basic concept
still applies. The actual current at the top of the coil is
somewhat higher than 0.707 amp because the current inside
the coil is greater than 1 amp. EZNEC says the current about
1/3 of the way up from the bottom of the coil is about 1.15
amp. The inductance of the coil forces the phase between
the voltage and current to increase. To maintain the same
V*I*cos(theta) power, the current must also increase.

The high flux fields developed inside the coil somewhat distort
the perfect current cosine wave found in a thin wire dipole so
it is not quite as black and white as ON4UN indicates.

You've caught Lord Kelvinator's ire, here. If you cannot state what
an S-point is, you have nothing to offer. There is absolutely no
guarantee that two test will fall on the same cardinal points on a
scale that is not monotonic. (Sorry this isn't in your English, but
you do claim to be a fella of the guys who measure things.)

Hi Reggie,

If you had read the thread instead of the wine label, you would see
this reporting of S-meters was from Mike, and confirmed by Roy (and so
would I with two more rigs, each with their variances).

What is lacking are YOUR data. Lord Kelvinator is winding up a pitch
to bounce another piece of chalk off your nappin' noggin'.

DUCK!

I hate to call a liar a liar, but sometimes it's hard to take. You're lying again, Reg.

I've never referred to my rig's meter as a calibration standard. I've used it as an example many times of a meter whose response is far from the 6 dB per S unit many people assume. It's my argument that any S-Unit "standard" at all is of no use, except by misleading people into thinking that it has some relation to the markings on their S meters. Mike's measurements serve the same purpose.

And you've claimed your rig has an adjustment allowing calibration of its S-meter to 6 dB per unit, but have never been willing to share the type of rig or what the adjustment control designation is. Frankly, I believe you're fabricating that, also.

It's sad -- you have a lot to offer, but somehow feel compelled to come up with pure fabrications from time to time. It makes some of us view everything else you say with some skepticism.

And you don't even need to read the present postings. This topic was beat to death in rather nauseating detail in November of 2003 -- see the "Current in antenna loading coils controversy (long)" thread in groups.google.com. It disgusted me because I spent a day setting up a test to make some careful measurements. Before reporting them, I asked Cecil, Yuri, and other proponents of various theories to use their theory to predict what the results would be. As you can see by reviewing the record, after being pushed, Cecil made a couple of different guesses but retracted them. Yuri didn't make any. I made the measurements, and Cecil immediately claimed that I had just proved exactly what he had predicted!

Then there was "More W8JI "wisdom" in August 2005. And now things must be getting boring again out in the Texas prairie, so here it comes again. Have fun, folks.

As you describe it, it does seem to be simple. But, the inner loop is made from coax and is flexible. Now I do plan to have a fiberglass pole, in the plane of the loop, which will connect the top and the bottom of the loop so as to give some rigidity to the outer loop. Perhaps this pole can also partially support the inner loop. In any case I do appreciate your advice and comments.

Roy, you are like the novice who uses a DC ohm-meter to measure
the feedpoint impedance of an antenna. You are using a lumped
circuit analysis in the presence of standing waves, not
realizing what an extreme technical blunder that really is.
Worse yet, you belittle people who point out your blunder.

Cecil,

I have lots of flaws, most of them unrelated to RRAA. But a lack of understanding of fundamental physical laws is not one of them.

Two points, and I won't carry on further.

* Who said anything about "steady state"?

* Current is generally accepted as the flow of charge. (If you know some other definition perhaps that is part of our disagreement.) When the current is different at the ends of a simple two terminal device then the charge flow is different as well. Since charge cannot be created or destroyed (I hope you have no argument with that) then it must be stored or depleted somewhere in that two terminal device. We most likely don't have chemical reactions going on in that device so the charge storage is facilitated through capacitance.

That is what Reg said. You disagreed. Reg is correct.

(No one is discussing power, phasors, degrees, distributed models or anything else you expounded on. Save it for another day.)

73,
Gene

This thread raises a possible marketing opportunity for someone. Yes,
it is quite unlikely, due to their non-linear construction, that an
analog meter would properly display S units in 6dB increments.

So..... someone ought to design a nice little digital unit that could
somewhat easily be hooked up to most radio Rx circuits, and be capable of
displaying S units or microvolts (selected at push of a button) and also
have a fully adjustable means to calibrate the S unit readings so that
they would, in fact, display in linear 6dB increments, and actual
microvolts at Rx input, too. Probably wouldn't sell cheap, but there
would be those hams who'd love to have such a device.

I suppose just a display for microvolts would suffice, though, and
that isn't hard to do at all. or just calibrate and re-paint the S meter
face to match...

Gene, you proved beyond any doubt, during the rest of your posting,
that you even though may quote the fundamental laws, you are
misunderstanding those fundamental laws. I think Richard Harrison
does understand. If you refuse to listen to me, then please listen
to him.

> Current is generally accepted as the flow of charge.

Standing wave current is a net charge flow of zero. Standing wave
current is DIFFERENT from traveling wave current. At any and every
point, the standing wave current is NOT moving. Since it is not
moving, there is NO net charge flow. Please read, understand, and
respond to the following simple example and questionaire:

Lossless Transmission Line, SWR is infinite

Ifor--> 1 amp <--Iref 1 amp

1. Is there any net flow of charge? _____

2. Is the current at a current maximum point equal to 2 amps? _____

3. Is the current at a current minimum point equal to 0 amps? _____

4. Is there any net flow of charge between the 2 amp point and the
zero amp point? _____

5. If I replace the 1/4WL section of wire with a 90 degree phase
shifting coil, have I changed very much? _____

6. If the current at one end of that coil is 0 amps and the current
at the other end of that coil is 2 amps, is there any net flow of
charge through the coil? _____

> When the current is different at the ends of a simple two terminal
> device then the charge flow is different as well.

That is definitely NOT true for standing wave current. There
is ZERO net charge flow for standing wave current. And standing wave
current is exactly what you are measuring in a standing wave antenna
like a 75m mobile antenna.

Richard,

You originally stated:

On page 99 of Terman`s 1955 edition of "Electronic and Radio Engineering" (my textbook was an earlier edition) is found the formula to convert the reflection coefficient into SWR or vice versa. These two parameters are innexorably locked together by formulas (4-22a) and (4-22b).

You are squirming away from the accuracy of your assertion that Terman calculates reflection coefficient from SWR, ie the "or vice versa" in your statement.

The reflection coefficient is a complex number with magnitude and phase, as you acknowledge when you later say "It is true that the reflection coefficient is a vector ratio of the reflected voltage to the incident voltage at the load".

In formula 4-22b of my copy of Terman, the term on the lhs is |rho|, which is the magnitude of the reflection coefficient.

No, you cannot calculate the reflection coefficient from SWR alone, but you can calculate the magnitude alone, but that is less information than the reflection coefficient.

To illustrate, and as you know, the reflection coefficient at a point can be used with the line propagation constants to calculate the impedance at another point on the line. You cannot do that with the magnitude of the reflection coefficient.

You have misrepresented Terman, he does not calculate the reflection coefficient from SWR (at least not in my copy).

Those diagrams were highly misleading, and have been withdrawn from the current 4th edition. That whole introduction to short verticals has been completely rewritten and revised.

The problem was that the current profiles of the full-size and loaded quarter-wave antennas were both drawn against a linear vertical scale of *phase*. This not only misrepresented the physical lengths of the lower and upper sections, it also misrepresented the length and effect of the coil. This presentation is highly misleading, and the first victim was the person who drew it, and then overlaid current profiles on it.

(I don't think this was ON4UN. When someone sets out to produce a 500-page book, they have to quote some things on trust from other people; and it may take a few editions to iron out all the kinks. Much more to the point, ON4UN is right at the leading edge of his subject, and each edition contains something new and important.)

The replacement diagrams in the 4th edition are much better. They show current profiles against *physical* height, and help bring out what's really happening.

>Current at the base of ON4UN`s whip is one amp times the cosine of
>45-degrees, or 0.707 amp. The loading coil has an input of one amp.
>
>With 1 amp into the loading coil and 0.707 amp out of the loading coil,
>the coil definitely does not have the same current at both ends.
>
You can't quite those figures in evidence, because they were never more than a speculation based on misunderstandings. When ON4UN came to think about it, he quite rightly changed his mind.

This brings up another point that hasn't been mentioned so far in this discussion: there is an important difference between purely inductive loading, and the kind of loading you can get from any practical inductOR.

Note the difference. An inductOR is a real-life electronic component, a coil of wire. InductANCE is its main electrical property - but it isn't the only one.

When a shortened antenna is loaded by pure inductance, you find the following:

1. The magnitude and phase of the current flowing into the loading inductance are both the same as that of the current flowing out (this is a fundamental property of pure inductANCE). This means the current distributions in the sections above and below the loading inductance join up in a sharp kink.

2. What does go through a step change is the *voltage* across the inductance. This changes in both magnitude and phase. For a typical centre-loaded whip, the RF voltage is low in all of the bottom section, but above the loading inductance it's very high indeed.

To repeat: this is the situation for loading with pure inductANCE.

(Sorry to keep shouting "ANCE!" and "OR!" like that, but I'll bet someone still comes back with a reply that proves they didn't read what I actually wrote.)

The diagram in ON4UN's 4th edition (Fig 9-44) shows these effects much better than I can describe them in words. The diagram came from an article by W7XC in QST for March 1990. I strongly recommend everyone to look at these diagrams... but please don't treat them as 'bible text'. Do your own thinking about it.

A different viewpoint on loading inductANCE is given in an article by Boyer in 'Ham Radio'. This uses the 'antenna-transmission line analog' theory... and comes to exactly the same conclusions about the effects of loading inductANCE: it is simply there to resonate the capacitive reactance that arises from having physically shortened the antenna. (Ironically, ON4UN's worked examples and computer programs to calculate loading inductance have always been based on this approach; the conceptual error in early editions was only in that one diagram.)

With a firm grip on the way that pure inductANCE loads an antenna, you are then in a good position to look at the differences that appear when you use a practical inductOR.

With a real-life inductOR, you don't have pure inductANCE any more. It is embedded in a component that is made from some length of wire, wound into a coil that has a physical length and diameter, has capacitance between its own turns, and also has capacitance to the straight sections of antenna above and below it. The effects of the coil's inductANCE will still be there, but you can certainly expect to see a lot of detailed differences.

But the practical differences can't possibly be understood without that basic understanding about inductANCE as a foundation. Without it, you're building your house on sand.

Just don't expect that the S-meter so "calibrated" is reading the real value of the incident field arriving at the rx antenna. It won't be, unless that calibration includes (exactly) the real-world performance of the receiving antenna system at each frequency, including line loss, local reflections, and other factors.

Otherwise the reading still will be given in fairly meaningless, relative terms -- the same as S-units.

That is a fundamental property of a pure inductance in a lumped circuit analysis which assumes a DC current or a pure traveling-wave current. It is NOT a fundamental property of a pure inductance if the current you are talking about is a net standing wave current. Your stated principle is simply false for a standing wave environment. In a transmission line, it is easy to install a coil that has zero current at one end and an amp of current at the other end.

It simply doesn't apply in a standing wave environment - and a 75m bugcatcher loaded mobile antenna is a standing wave antenna. Please take a look at my example and questionaire to understand what is wrong with your above statement.

The measured current at the bottom of a loading coil is primarily standing wave current. IT IS NOT FLOWING.

The measured current at the top of a loading coil is primarily standing wave current. IT IS NOT FLOWING.

Since neither of these two currents are flowing, they don't have to be equal. They just stand there.

If I present to you a black box with zero amps at one terminal and one amp at the other terminal, what can we conclude? One possibility is 1/4 wavelength of coiled up coax with an infinite SWR. Please ponder that and apply it to your coil assertion above.

The currents that are doing the flowing are the underlying current components, the forward current and the reflected current and they are close to equal. Everything you say about a coil is true for the forward current and the reflected current. It is simply not true for the standing wave current which is just a conceptual construct and not a flowing phasor at all.

If you really want to accurately apply the principles you are asserting, you must treat the forward current and reflected current separately and then superpose the results. Applying your above principle to standing wave current is akin to superposing power and that's a no-no.

I have never seen such a wide-spread blind spot.

Take the transmission line example.

```
---------------------------X----------------------------
Ifor=1.0amp --> <--Iref=1.0amp
```

There's a black box at 'X'. Inside the black box is 1/4WL
of coiled up transmission line. The current measured at
left of the black box is zero amps. The current measured
at the right of the black box is 2 amps. That doesn't
violate any laws of physics. That obeys the laws of physics
for a transmission line with reflections. You are measuring
the currents at a current node and at a current loop. It's
absolutely no big deal.

The bottom line for the Rx, all it cares about since it doesn't know what kind of antenna is feeding it, is the signal strength at the input.... so I'd say a calibrated microvolt reading reflecting that strength is not very meaningless at all. Any changes in the antenna system will of course change that, but the whole point of any antenna work is to maximize the signal voltage to that rx input, so I'd think a calibrated reading would be extremely useful over an S meter alone.

I'm afraid it might require more than simple calibration. The S-meter typically just shows the AGC voltage. The AGC response is only approximately logarithmic, and depends on the gain characteristics of the various stages being controlled. Gain characteristics are commonly very temperature sensitive, so any calibration scheme would have to take that into account, as well as the common deviation from true logarithmic response of the various stages. Calibration would also be different on different bands, with and without preamplifier or attenuators, etc.

Of course, you could make a receiver with very nearly true logarithmic response, by use of one of the excellent, wide dynamic range log amps which are available these days. But however much you or I might like one, the vast majority of amateurs couldn't care less about what their S meter is really indicating, so they wouldn't pay the added cost for it.

On top of that, most amateurs would consider a 6dB-per-S-unit meter to be "dead", and would rather have it wiggle more.

Chris,

I'm not sure exactly what you need. Are you working with microwave
frequencies?

I have some type N connectors that house a 1N21 and have a BNC on the
rear. Presumably it's simply a series diode used as a detector.

I fully agree with Roy's comment about the AGC-derived S-meter output. As he says, the AGC characteristics are temperature dependent, and they are also dependent on the particular set of active devices (and to some extent the passives too) in the signal path.

If you have access to a spectrum analyzer, chances are decent that it will have a well-calibrated amplitude readout. The one I use is accurate in a relative sense to a fraction of a dB over more than an 80dB range, and would certainly be sensitive enough for antenna comparisons. I suppose both those would be true of most modern spectrum analyzers. In addition, some are quite good at determining the total power in a specified frequency range, and if you can find such a range with no signals, you can get a better reading on noise than you're likely able to do with an S meter, or even a narrow band spectral measurement.

Cheers,
Tom

One of the most complex and difficult parts of a spectrum analyzer to design is the log amp which provides this stable and precisely logarithmic response over a wide dynamic range. There's an incredible amount of really ingenious work on the part of some extremely talented engineers in those circuits. In relatively recent times, Barrie Gilbert and his folks at Analog Devices have done some equally clever work in the design of IC log amps. It's not a trivial task by any means.

So true, that last part! Well, I certainly understand the non-linearity of the RX when comparing gain accross the entire HF spectrum. I tend to limit my operations to top band and 75, so I hadn't considered changes in Rx gain when moving down the band (or up, as some would have it). Currently, when I do an Rx calibration, I just take some readings on my "S" meter when injecting a signal in the bands of my concern. A "list" of these readings for each band suffices, although I agree with you that that is far more than most hams would bother with.

Cecil,

A few questions.

Do you have a reference that explains this "net standing wave current
that does not flow"?

Does this magical current have any other interesting properties besides
the lack of charge flow?

Do ordinary properties such as inductance and capacitance cease to
function when dealing with "net standing wave current"?

Do you really think it is a good idea to base detailed numerical
analysis on these "conceptual constructs" as you call them?

Do you have a convenient listing of your "conceptual contructs" so that
we can avoid these battles in the future?

8-) 8-)

yes, any em wave will be shifted in frequency/wavelength when there is a relative velocity between the tx and rx.

doppler shift is NOT 'a tone frequency'. it may be heard as a tone in a receiver if you beat it against a fixed local oscillator. But the doppler shift does not modulate the wave or change the type of modulation that may already be imposed on the wave by the transmitter.

now if you are talking about a doppler direction finder system... those work best with unmodulated signals, but will work with modulated signals but may have difficulty getting reliable directions, especially if the modulation frequency is near the rotational frequency of the array.

Received signal strength, whether in terms of relative S-units or the measure of real incident fields, is at least as much the result of local conditions as of the ERP of the transmission source on the path toward the receiver, the frequency, and propagation conditions.

So the received signal strength indication, whether relative or "real," isn't a hugely significant indicator of any of these parameters.

I'm sorry, but those last three paragraphs are simply contradictions in terms, which demonstrate their own illogicality.

Electrical current is defined as a net rate of transfer of electrons, so by the very definition of the term there is literally no such thing as a non-flowing current (except when the current is exactly zero and the definition becomes moot).

I seriously wonder if you understand what a standing wave is. It is simply a pattern of variation in current along the length of a transmission line, which is stable in time.

If you pick any point along the transmission line or antenna wire,
there is a simple net current characterized by one amplitude and one
phase, relative to some other reference point. (In this whole discussion
we discount the normal cyclic sinusoidal variation of instantaneous RF
current which is happening everywhere in the system.)

In our minds, we may choose to explain the causes of the standing wave
by resolving the net physical current into conceptual forward and
reverse components; but the physical system doesn't know what you are
thinking. To be valid, your concept must do nothing more than explain
what's seen to be happening; it cannot seek to affect it.

At the point where you have to say that a measured (and therefore
measurable) current does not flow, your concept is in trouble.

>If I present to you a black box with zero amps at one terminal
>and one amp at the other terminal, what can we conclude? One

Your length of coiled up coax is a FOUR-terminal device, like Richard's
transformer was. It isn't an applicable solution for this problem.

It is entirely *your* responsibility to ensure that your postulated
forward and reflected currents obey the same circuit laws as the
physical net current. If you cannot do that, your concept fails.

The laws it violates are those of logic. Your black box is not allowed
to sometimes have two terminals and sometimes need four.

>That obeys the laws of physics
>for a transmission line with reflections. You are measuring

Sorry, I just don't see it. But what I do see are the contradictions and
inconsistencies of logic that you are forced to resort to, in order to
arrive at the conclusion you've already decided upon. I think that
proves the exact opposite.

Gene Fuller wrote:
> Do you have a reference that explains this "net standing wave current
> that does not flow"?

No, this is one of those topics that is supposed to be "obvious
to the most casual observer" and not worthy of further comment.
Why it is not obvious to you and others is beyond belief. Some-
thing terrible has happened to the educational system since 1957
when I learned all these principles at Texas A&M. I assume that
this is just a part of the "dumbing down" of the educational
system that I keep hearing so much about. Incidentally, these
concepts are obvious to Walter Maxwell.

> Does this magical current have any other interesting properties besides
> the lack of charge flow?

It's not magical but yes, it's phasor value (if it has one)
doesn't rotate which is prima facie evidence that it doesn't
flow. Any flowing phasor has a rotation of omega (2*pi*f).
The fact that standing waves don't have a rotation is proof
that they don't flow. To tell the truth, standing waves are
a product of the human mind. The forward and reflected waves
couldn't care less about standing waves. Last time I talked
to them, they didn't even know that each other existed except
for the points in the transmission line where their constructive
interference causes the wire to heat up. :-)

Surely you understand that standing waves in a transmission line
don't flow - they just stand there, which is why they are called
"standing waves". Exactly the same principle applies to standing
wave antennas.

> Do ordinary properties such as inductance and capacitance cease to
> function when dealing with "net standing wave current"?

No, but one has to exercise caution and invoke the superposition
principle to ascertain what is happening. The two traveling waves
have to be analyzed separately and then superposed to obtain valid
results. If you analyze net current without superposition, you are
doing the same thing as superposing powers, which is a known no-no.

> Do you really think it is a good idea to base detailed numerical
> analysis on these "conceptual constructs" as you call them?

All human thought is based on conceptual constructs. That's what
makes us different from the rest of the animals. If you don't
like "conceptual constructs", then go swim in a zoo pool with

the alligators. :-)

> Do you have a convenient listing of your "conceptual contructs" so that
> we can avoid these battles in the future?

Only dealing with one at the moment, Gene. The lumped circuit
model falls apart unless you first apply it to the component
currents and then superpose. The distributed network analysis
was developed to avoid that very problem. So the only valid
choices are to either use the lumped circuit analysis on the
component currents and then superpose or use the distributed
network analysis which, in the end, boil down to the same thing.

>just wanna confirm.
>u were saying we can still get a reliable doppler shift from a
>modulated signal be it analog or digital?
>thank u so much

Yes.

The Doppler frequency equals the rate of change of the distance
expressed in wavelengths. Thus the Doppler shift is a function of
carrier frequency and relative speed difference. It doesn't matter one
bit (no pun intended) what the modulation, if any, is.

Many tactical Radars for instance use pulse/Doppler to determine both
range and rate of closure. An example that I'm most familiar with was
in the Phoenix Missile. The early variant used a pulsed klystron PA
and all analog signal processing. The pulse repetition frequency
(prf) and duty cycle were fixed and I suppose are still classified,
although the missiles are now retired (sob).

http://www.fas.org/man/dod-101/sys/missile/aim-54.htm

The Doppler is typically determined by having a bank of Doppler
filters (at i-f) and looking in each one for the returned signal.
Either the transmitter TO or the receiver LO, but not both, is then
adjusted to put the returned signal in the center filter. In the old
analog system, the VCO(s) were linearized so that the tuning voltage
was an indicator of the Doppler.

With pulse modulation this can get more complicated because there are
modulation sidebands spaced at the prf above and below the nominal
carrier frequency. If the Doppler is greater than the prf then it's
possible for a carrier sideband +/- Doppler to fall into the Doppler
filter bank and it takes some more manipulation to sort this out.

With the digital processor in the later variants the Doppler filters
were realized in software.

Now, aren't you sorry you asked? :-)

Yes, I realize that. Do you realize that the characteristic
impedance of a single #14 wire 30 feet above ground is 600
ohms? That pesky ground return path raises its ugly head once
again. It's impossible to install a two-terminal system 30
feet above *ground* and have it remain a two-terminal system.
It's only a two-terminal system in your mind.

> Electrical current is defined as a net rate of transfer of electrons, so
> by the very definition of the term there is literally no such thing as a

You have hit the nail squarely on the head without realizing it.
A non-flowing current doesn't exist in reality but that is exactly
what you are measuring when you measure standing-wave current.
The only things that exist in reality are the forward and reflected
current. So you guys are basing your high and mighty concepts on
something that doesn't even exist in reality. No wonder you are
confused. You are measuring two currents flowing in opposite
directions at the same time and don't realize it.

> I seriously wonder if you understand what a standing wave is. It is
> simply a pattern of variation in current along the length of a
> transmission line, which is stable in time.

Nope, that's not what it is. For example, a current standing
wave on a particular transmission line is the sum of one amp
flowing in one direction and one amp flowing in the opposite
direction. Exactly what is the net charge flow when identical
currents are flowing in opposite directions? Let's see now,
this is a really tough one. One amp flowing in one direction
minus one amp flowing in the opposite direction. What could
the result possibly be? :-) Hint: think DC to see what the
net charge flow would be.

> If you pick any point along the transmission line or antenna wire, there
> is a simple net current characterized by one amplitude and one phase,

I suggest you review traveling wave phasors which rotate at omega
(2*pi*f). A standing wave 'phasor' doesn't rotate at all so a standing
wave current is not moving. I'm not even sure it is technically valid
to call a standing wave current a "phasor" since it doesn't even possess
a frequency characteristic. Please think about a perfectly stationary,
non-revolving 'phasor' and then comment. Wouldn't a non-revolving
phasor be DC?

> To be valid, your concept must do nothing more than explain
> what's seen to be happening; it cannot seek to affect it.

The same thing applies to your concepts. So what do your concepts
say about a phasor with an omega(2*pi*f) equal to zero as is the
case for standing waves? Are standing waves really DC? Do they
exist at all anywhere besides the human mind?

> At the point where you have to say that a measured (and therefore
> measurable) current does not flow, your concept is in trouble.

Sorry, I have absolutely no idea what that means. Surely you have
measured zero current at a standing wave current minimum where the
forward current equals one amp and the reflected current equals
one amp. Is that zero amps in the act of flowing?

> Your length of coiled up coax is a FOUR-terminal device, like Richard's
> transformer was. It isn't an applicable solution for this problem.

If you include that pesky ground under antennas, it is. My electronics
equation book contains a formula for the characteristic impedance
of a single wire transmission line over ground. Is that invalid?
Doesn't that sound very much like a dipole wire in the air?

> The laws it violates are those of logic. Your black box is not allowed
> to sometimes have two terminals and sometimes need four.

An antenna system installed on this earth is always a four terminal
system whether you like it or not. Haven't you ever seen those diagrams
of the current return to ground from an antenna system?

I'm sorry, I forgot to provide a reference for your
non-existant non-flowing current. On page 464 of
"Antennas for All Applications", by Kraus and Marhefka,
3rd edition, it shows the current on a 1/2WL dipole along
with its phase. The phase is *fixed* at zero degrees over
the entire 1/2 wavelength. So what does an RF current
with a fixed phase of zero degrees really mean? It means
that the 'phasor', if it is indeed a phasor, doesn't
flow. How could an RF current with a fixed phase of zero
degrees manage to flow? e^wt would be zero.

Back many years ago, and probably still today, many hams would turn
away from a receiver that had what they called a "scotch" S meter. To
them a receiver that read S 6 while another receiver only read S 4 on
the same signal "had to be much better". Manufacturers started making
receivers with more lively S meters.
Looking at some of the older receivers such as the Collins had much
more realistic S meters than most today.

The calibration points that Mike did on his receiver should be valid
for any band for his antenna comparisons. An actual signal strength
measurement is not required nor would it be valid between bands. All
that is really needed is the difference measurements between the two

antennas so his calibration between points on the meter scale will be valid on any band.

A really nice instrument that would be good for signal strength measurements is an old HP 3586C selective level meter. It covers from around 100 hz to 32 Mhz and has a digital readout to 2 decimal places in dbm signal strength. Hard to use with other than a steady signal though.

Owen Duffy wrote:
"In formula 4-22b of my copy of Terman, the term on the lhs is Irhol which is the magnitude of the reflection coefficient."

In my copy, 4-22b gives the "absolute value" of the reflection coefficient (it is embraced with bars) which I believe means the "absolute value" of a number or a symbol without reference to its algebraic sign.

(4-22b):
+or- reflection coefficient=
SWR-1 / SWR+1

These formulas, (4-22a) and 4-22b) aren`t just theory. They are constantly put to use. A derivation which uses the sq rt of the ratio of refllected power to forward power for the reflection coefficient appears on page 23 of my Bird Model 43 Directional Thruline Wattmeter Manual.:
SWR = 1+reflection coefficient / 1-reflection coefficient
(Same as 4-22a)

Transmission lines are special because they enforce Zo. That is, in either direction of travel, when you apply a voltage to the low-loss line, the current which results is locked in-phase with the applied voltage. In other words, Zo is a resistance.

Best regards, Richard Harrison, KB5WZI

I'm not sure I fully understand this. The difference from one S meter division to another *is* likely to be different on different bands, since it depends on the gain-vs-voltage characteristics of the controlled stages which can vary with frequency. But I do agree that he can make good comparative antenna measurements without good S meter calibration, because he has a step attenuator. By simply setting the attenuator so he gets the same S-meter reading on both antennas, S-meter calibration is completely irrelevant -- the antenna gain difference is the attenuator setting.

I find it useful, however, to be able to see the difference with reasonable accuracy just by looking at my S meter. But that does require calibration for the band in use.

Sun's next 11-year cycle could be 50 pct stronger
Mon Mar 6, 2006 3:49 PM ET

By Deborah Zabarenko

WASHINGTON (Reuters) - Sun-spawned cosmic storms that can play havoc with earthly power grids and orbiting satellites could be 50 percent stronger in the next 11-year solar cycle than in the last one, scientists said on Monday.

Using a new model that takes into account what happens under the sun's surface and data about previous solar cycles, astronomers offered a long-range forecast for solar activity that could start as soon as this year or as late as 2008.

They offered no specific predictions of solar storms, but they hope to formulate early warnings that will give power companies, satellite operators and others on and around Earth a few days to prepare.

"This prediction of an active solar cycle suggests we're potentially looking at more communications disruptions, more satellite failures, possible disruptions of electrical grids and blackouts, more dangerous conditions for astronauts," said Richard Behnke of the Upper Atmosphere Research Section at the National Science Foundation.

"Predicting and understanding space weather will soon be even more vital than ever before," Behnke said at a telephone news briefing.

The prediction, roughly analogous to the early prediction of a severe hurricane season on Earth, involves the number of sunspots on the solar surface, phenomena that have been monitored for more than a century.

TWISTED MAGNETIC FIELDS

Every 11 years or so, the sun goes through an active period, with lots of sunspots. This is important, since solar storms -- linked to twisted magnetic fields that can hurl out energetic particles -- tend to occur near sunspots.

The sun is in a relatively quiet period now, but is expected to get more active soon, scientists said. However, there is disagreement as to whether the active period will start within months -- late 2006 or early 2007 -- or years, with the first signs in late 2007 or early 2008.

Whenever it begins, the new forecasting method shows sunspot activity is likely to be 30 percent to 50 percent stronger than the last active period. The peak of the last cycle was in 2001, the researchers said, but the period of activity can span much of a decade.

The strongest solar cycle in recent memory occurred in the late 1950s, when there were few satellites aloft, no astronauts in orbit and less reliance on electrical power grids than there is now.

If a similarly active period occurred now, the impact would be hard to predict, according to Joseph Kunches of the National Oceanic & Atmospheric Administration's Space Environment Center in Colorado.

"It's pretty uncertain what would happen, which makes this work more relevant," Kunches said.

"What we have here is a prediction that the cycle is going to be very active, and what we need and what we're of course working on is to be able to predict individual storms with a couple days or hours in advance so the grids can take the action," Behnke said.

My obviously-overloaded must-be-pea-sized brain sure has trouble thinking
of current which is NOT flowing, since my basic internal definition of
"current" is something like "electrons flowing past a point".

I'm enjoying reading this thread, but, what with all the difficulties
my brain is having with such subtle points, I'm NOT learning much!

A coil inevitably occupies space.

In particular, one of its dimensions is length.

Therefore it can be, and indeed for accurate modelling always should be, treated as a component having distributed L, C and R.

It just makes the mathematics somewhat more complicated. Hyperbolic functions can be involved.

Like a transmission line, a coil possesses Zo, phase-shift, attenuation and Q.

It is why my coil-loaded antenna programs provide answers in the right ball-park although I havn't a clue about the rules which govern the American ball game.

By the way, reflections and standing waves are irrelevant and don't enter the argument. Sorry Cecil!

Reg, G4FGQ.

Myron,

I'm afraid Cecil has a fixation about standing waves and reflections.
He brings them into arguments on every possible occasion.
Nevertheless he is very convincing and manages to drag most people in.

Give your brain a rest. Visit your nearest barber shop and tune up.
You will feel much better.

Reg.

Myron A. Calhoun wrote:
"--I`m not learning much."

Alas, I`d wager I don`t have anything new for Professor Calhoun, but from some of the postings, what I write may be new in part to someone.

Current is defined as movement of electrons through a conductor. Obviously, an incomplete definition. As we know, there is beam current in the vacuum of a CRT, and that at r-f, skin-effect forces most electrons to the surface so that most electron movement is on or very near the surface of the conductor rather than "through" it.

When currents of equal amplitude and opposite direction meet at various points along a perfect transmission line, as they might after a perfect reflection of the incident wave, one might measure zero amps at cancellation points along the line. These would be distributed periodically as the waves, in fixed phase relation and equal and opposite currents, coincide. The measurement of zero amps occurs because the ammeter is measuring both currents simultaneously. If a directional coupler is used to measure the current in each direction separately, it will be found that the currents traveling in opposite directions are passing through each other without effect. Standing waves are more manifestation than anything else.

There was a PBS TV Channel appeal tonight. It Quoted Einstein as saying: "Nothing happens until something moves".

Incident and reflected waves move on a transmission line but standing waves are stationary and don`t move. So, it is the incident and reflected waves that make something happen. Not the stationary waves.

Circulating energy within a transmission line causes standing waves. Without a reflection, they don`t exist. Energy must be accepted by an antenna to be radiated. It is best if it is accepted on the first pass so that there are no more losses on additional passes. A perfect match at the antenna accepts energy on the first pass. A mismatched antenna produces an SWR. Magnitude of the SWR is an indication of how much mismatch there is.

Best regards, Richard Harrison, KB5WZI

Forward current is a traveling wave and is flowing. Reflected
current is a traveling wave and is flowing. Both can be
represented by phasors. But since they are traveling in
opposite directions, their phasors are rotating in opposite
directions and their superposed sum always add up to the
same constant phase angle = zero (in a thin wire).

Given a 1/2WL (-90 deg to +90 deg) thin wire dipole fed in
the center (at 0 deg) with 1.0 amps, the standing wave current
magnitude on the antenna is cos(theta) and the phase angle
is a constant zero degrees from end to end. Reference: Figure
14-2, page 464 of "Antennas for All Applications", by Kraus
and Marhefka, 3rd edition.

If the phasor sum of two currents is not rotating, it is not
flowing. Since phasors, by definition, change phase at a rate
of (2*pi*f) and the standing wave current doesn't change
phase at all, I don't think standing wave current is a phasor.
Standing wave current is what we measure on a standing-wave
antenna like a 75m mobile center-loaded bugcatcher.

> manifestation than anything else.

And this is equally true of standing wave antennas. Kraus goes
as far as assuming the forward and reflected currents on a
1/2 wavelength thin-wire dipole are equal in magnitude so
they must be close to equal in magnitude. I have estimated that
the magnitude of the reflected current after the round trip
to the end of the dipole and back to be in the ballpark of
90% of the forward current at the feedpoint.

This entire episode of constant current through a loading coil
is the result of thinking standing wave current flows. As you
say it is a manifestation of our thinking process and our
measurements. It doesn't flow at all.

Incidentally, a horizontal dipole above earth can be analyzed
as a single-wire transmission line system with the earth being
the ground return path. Balanis says, "Standing wave antennas,
such as the dipole, can be analyzed as traveling wave antennas
with waves propagating in opposite directions (forwards and
backwards) and represented by traveling wave currents If and Ib
in Figure 10.1(a)."

The forward current (If) through a loading coil is very close
to constant magnitude. The reflected current (Ib) back through
a loading coil is very close to constant magnitude. Their
phasor sum is the standing wave current that we measure. There
is no physics requirement that the phasor sum of the forward
and reflected currents be of equal magnitude on both ends of
the loading coil.

>+or- reflection coefficient=
>SWR-1 / SWR+1
>
Richard, you seem to be dealing with reflection coefficient as a real number when in fact it is a complex number. Your definition of |rho| is inadequate when rho is complex.

Terman actually says in the preceding text "The standing wave ratio S is one means of expressing the magnitude of the reflection coefficient; the exact relationship between the two is..."

Your statement "On page 99 of Terman`s 1955 edition of "Electronic and Radio Engineering" (my textbook was an earlier edition) is found the formula to convert the reflection coefficient into SWR or vice versa. These two parameters are innexorably locked together by formulas (4-22a) and (4-22b)." is wrong where it says "convert the reflection coefficient into SWR or vice versa" in respect of the "vice-versa" because you ignore the fact that the reflection coefficient is a complex quantity, and that the "magnitude of reflection coefficient" is not the same thing as "reflection coefficient. You cannot calculate the reflection coefficient from the SWR (except of course the special case where SWR=1).

You have cited Terman in support of your own loose words, but Terman's words are more carefully chosen and correct, yours are not, and the Terman reference does not support your misconception at all.

Owen

I'm curious, Reg. With traveling wave energy flowing in both
directions through a loading coil, how do you analyze it
without taking the forward and reflected energy into account?
All my reference equations have a term with a positive exponent
for forward current and another term with a negative exponent
for reflected current.

Reg Edwards wrote:

> I'm afraid Cecil has a fixation about standing waves and reflections.

They are part and parcel of a distributed network analysis
and are embedded in many transmission line equations.

As far as the constant current through the coil goes:

Neglecting losses, the forward current through a coil is
constant magnitude with changing phase. The reflected
current through a coil is constant magnitude with changing
phase. Those conditions satisfy the necessary and sufficient
conditions of the laws of physics concerning a coil.

The laws of physics do not require the phasor sum of the
forward current and reflected current to be constant
magnitude. In fact, the laws of physics prohibit the
standing wave current from being equal magnitude except
at equidistant points from a current maximum or minimum.

Anyone know how to use square rod in modelling programs?

I'm sure it's a small effect, but I'm interested in the *proper* way to account for it vs. round rod.

I've used the mean radius of the inscribed and circumscribed circles and that turned out fine,
but I don't have much ability to make good gain and F/R measurements.

It seems that the corners could affect element coupling...

Should I use the circle that has the same area? Maybe the geometric mean of the radii of the inscribed and circumscribed circles?

I've got a bunch of 1/4" square rod that I want to make 435MHz yagis out of, and pretty much all web searches I could think of on square antenna elements either get zero hits for being too specific or talk about quads a lot.

The square rod is great mechanically; I can slap a piece of PVC pipe on a milling machine, mill 1/4" slots through very accurately spaced, and hold the elements in with cable ties.

Anyway, I'm just going to try the geometric mean and build another antenna, but I'm interested in any comments on this.

Hi Miken

I've been using the tubular, high permeability ferrites designed for RFI suppression slipped over the RG-223 coax for a balun for vhf antennas. I am aware of the high loss with those ferrite tubes. I have been hoping the high permeability would present a high reactance to currents along the outside of the coax. So far, the tubes are working OK for my needs. Your mileage may vary.

Jerry

As they say, measure with a micrometer, mark with a crayon, and cut with an Ax. From my limited (50 years) experience, your picking fly crap out of pepper!

The absolute perfectly modeled antenna will still have to be adjusted in it's environment. The difference between square and round tubing is insignificant unless your into the mental masturbation of caring everything out to 12 decimal places.

I am sure that someone will venture forth with an example to show how important this is at some frequency, altitude, temperature, phase of the moon and barometric pressure.
Such is the habit of the newsgroups denizens.

The reality is YOU have square tubing, use it and enjoy the contacts.

2153. Re: does doppler systems work only for unmodulated continous wave signals?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-07 16:07:46 UTC
From: Bob Bob <bob3bob3@cox.net>
Message-ID: <inn0e3-ue2.ln1@p400bob.personal.cox.net>
Source record: 63718

You know I am not quite sure how to answer that..

Doppler shift is a relative thing. If you are travelling at 100kph the signal/carrier whatever relative to you is unaffected. Relative to a RX that is relatively moving either towards or away from you a shift will be apparent.

The entire transmitted spectrum will be affected, not just the "carrier". There will of course be a calculable difference in shift over the bandwidth of the signal as the lower end will shift less than the upper one more. Whether it will be a significant amount or not depends on your application. A +- 10MHz wide signal at 2.4GHz for example (100kph) would be close to an extra 1Hz of shift at the signal edges.

As your relaitive velocities approach the speed of light other problems crop up. I dont quite remember Einstein's stuff on this. Since though I doubt I'll never get to experiment with it I dont need to go through it again!

Is that what you were looking for?

Cheers Bob VK2YQA

2154. Re: Current through coils

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-07 16:14:26 UTC
From: w8ji@akorn.net
Message-ID: <1141748066.033150.267940@v46g2000cwv.googlegroups.com>
Source record: 63714

Cecil Moore incorrectly posted:

<W8JI measured a 60 degree phase shift through a 100uH coil
<at 1 MHz. Consider that at one end of that coil the
<forward and reflected currents may be:
<Ifor = 0.55 amps at zero deg, Iref = 0.45 amps at zero deg.

<Inet = Ifor + Iref = 1 amp at zero degrees.

<At the other end of the coil, the forward and reflected
<currents may be:

<Ifor = 0.55 amps at +60 deg, Iref = 0.45 amps at -60 deg
<Inet = Ifor*cos(60) + Iref*cos(-60)

<Inet = 0.275 + 0.225 = 0.5 amps at zero deg

The above analysis clearly shows how wrong Cecil is, and how he invents reasons to support things.

I NEVER measured a current shift of 60 degrees, and I never said I measured a current difference of 60 degrees.

The phase shift I measured was in VOLTAGE. It simply shows the voltage is out of step with the current. It doesn't indicate current is shifted 60 degrees between each inductor terminal at all, and I never said it did.

The current level at each end of the inductor was, as far as I can measure with test equipment, equal.

This is another clear case of Cecil taking things out of context and mixing them with his idea that an inductor treats current differently, depending on what direction it "flows" (or whatever he is claiming, I certainly can't make sense of his arguments).

It is always better to let people directly post what they say, and not have it run through a "Cecil Moore" filter.

Conventional wisdom cautions against sharp bends in open wire transmission line. What is the practical/quantifiable effect of violating this rule?

How does the effect vary with the severity of the bend and does it vary with the distance along the line at which the bend occurs?

Tnx es 73, AL.

Not hard to do if you think in terms of a Klystron tube. Although it
might not directly use Doppler within the stretch of its beam current,
the tube structure is quite decidedly built for speed of light and
wavelength bunching. Hop in a car with one and you got your 100 kM/h.

Walla (as the french say) you've built your own speed trap radar
beacon.

Hi OM,

You've got too many factors running through this. For one, digitally
modulated is not digital data mode (FSK). There are a world of
modulation types and some are strictly derived from a bit stream (not
all bits equal in width either). Sometimes even the carriers are
digitally derived (not a sine wave).

Doppler is going to give rise to dispersion (often a term confined
these days to fiber optics, but whose derivation arose from waveguides
- LF Optics).

> did.

The subject was Kraus' 180 degree current phase shifting coils. Here
are you exact words (and all of your words about that measurement)
quoted from qrz.com:

> By the way, I swept S12 phase with my network analyzer on a 100uH
> inductor a few hours ago while working on a phasing system. The
> phase shift through that series inductor was about -60 or -70 degrees
> on 1 MHz, crossing ZERO phase at self resonance (where loss became very
> high) near 18 MHz, and gradually increasing leading phase above 18MHz
> reaching 90 degrees and staying there well above resonance.

I apologize for missing the small detail that S12 was a voltage
measurement rather than a current measurement but I'm sure you can
see how that was an honest mistake and easy to make. You didn't
mention "voltage" at all in your posting and the context was current.
I didn't recall until your objection here today that S12 is a voltage
parameter measurement.

But that leads to a question. Why were you using voltage measurements
to try to disprove Kraus' statement about 180 degree current phase
shifting coils. Quoting from: "Antennas for All Applications", Kraus
and Marhefka, 3rd edition, page 824: "A coil (or trap) can also act
as a 180 deg (current) phase shifter as in the collinear array ...
The coil may also be thought of as a coiled-up 1/2WL element."

> The current level at each end of the inductor was, as far as I can
> measure with test equipment, equal.

That sure doesn't make technical sense. If there was no phase shift
in the current, then the voltage was lagging the current. But we know
the current lags the voltage through an inductor by as much as 90
degrees in the ideal case. If the voltage is delayed by 60 degrees,
then the current must necessarily be delayed by 60 degrees plus the
lag to satisfy the laws of physics. If you will run the experiment
using current probes, I assure you that the current will experience
more of a phase shift than the voltage, just as the laws of physics
predict. Which means there was more than a 60 deg current phase

shift through the coil which makes my argument even stronger.

Now, if you are talking only about the magnitude of the current then
of course, the current was equal at both ends of the coil because
reflected energy was absent for that measurement. IT IS THE PRESENCE
OF REFLECTED ENERGY THAT MAKES FALSE YOUR ASSERTION ABOUT NET CURRENT.
I think we are in perfect agreement about systems without reflections.

> This is another clear case of Cecil taking things out of context ...

Not out of context, Tom. The entire quote is just above. The mistake
was an honest one and easy to make. I'm only human. :-)

> and
> mixing them with his idea that an inductor treats current differently,
> depending on what direction it "flows" ...

Sorry, I never said that. An inductor treats forward waves and
reflected waves exactly the same according to the laws of physics.
Your statement is more akin to your idea that standing wave current
flows into the bottom of a coil and out the top. The coil treats all
traveling waves exactly according to the laws of physics and exactly
as you and I understand those laws of physics. I accept everything
you say about traveling wave current through a coil. My argument with
you is that a standing wave current is not a traveling wave current
and doesn't behave like a traveling wave current. That seems rather
obvious to me.

1. Just as you say, the forward traveling-wave current through a coil
is of constant magnitude. Here's what Walter Maxwell says: "If an
inductance is in series with a line that has no reflections, the current
will be the same at both ends of the inductor." All three of us agree on
that statment.

2. As in (1) above and just as you say, the reflected current through
a coil is of constant magnitude.

3. There is no law of physics that requires the standing wave
current to be equal at the top and bottom of a coil. In fact,
such a requirement violates those laws of physics. Here's what
Walter Maxwell says: "If an inductance is
in series with a line that has reflections, the current will NOT be
the same at both ends of the inductor. Consequently, circuit analysis
will not work when both forward and reflected currents are present
in a lumped circuit. When reflections are present, a current node
and a current loop can appear at separate points on an inductor
simultaneously." Judging from what he has posted earlier, Richard
Harrison agrees with those statements.

There's an EZNEC graphic at: http://www.qsl.net/w5dxp/qrzgif35.gif

Would you have us believe that 0.1+ amps is flowing into the bottom
of the coil and 0.7+ amps is flowing out of the top of the coil?

It is your concept that standing wave current flows that is the
problem. Please explain how a current with a zero phase angle
from tip to tip on a 1/2WL thin wire dipole can possibly flow without
a rotating phase angle.

> It is always better to let people directly post what they say, and not
> have it run through a "Cecil Moore" filter.

I agree, Tom, but you were not posting here so I quoted what I honestly
thought you said over on qrz.com. I quoted the same thing on qrz.com over
a number of days. You could have pointed out my mistake a lot sooner and
saved me from making it here.

Hi Al,

This arises from two concerns, with all probability that neither will
bother you.

1. High power presents an arcing opportunity (very high power, pulsed
100s of KW);
2. Accuracy of determining a load.

The usual response is to confine your bends to a quarter wave sweep.
Now, if it really mattered (a lot) just imagine your problems at 160M.

Fred,

You are absolutely right as far as my particular antenna goes....
changing the element size by a couple of mm doesn't do anything at all
to the antenna I'm going to build.

But for high frequencies with relatively fat elements and close
coupling, maybe it does matter.

This is a question about theory; it *is* a question about the twelfth
decimal place (or is it the third? the fourth? the second?)

I'm going to build it anyway. I'm going to get on FO-29 and make
contacts with it.

I just wonder if there's a *right* way to plug square elements into
antenna modeling programs. There certainly is a right way to account
for tapered elements.

I think it would be better if Walt represented himself, unless he ASKED you to post that Cecil.

Why not let Walt post what he thinks rather than someone else telling us what Walt thinks? We each should speak for ourselves and let other people speak for themselves. If Walt has something to say, I'm sure he will chime in.

Drumming up support by writing what we **think** others say or mean seems pretty desperate.

All of that aside, what does it matter who agrees or disagrees? Things work they way they work. All reliable measurements I've seen disagree with Cecil's theory.

I can't believe anyone with experience in RF systems would think a physically small inductor (small in terms of wavelength) would have significantly unequal currents in the inductor or in the terminals of the inductor, especially any difference caused by "reflected waves".

It does allow me to make a stab at comparing those two antennas. As I continue on this test, it would be nice to have something that has some sort of calibration. Otherwise we might as well just go to say "works great" or "doesn't work well for all measurements.

And in this case, it really isn't necessary. I simply need some
baseline to start my readings from.

Already I have noticed that different stations come in at different
strengths - presumably on the basis of propagation differences. There
may be some differences over time scales of minutes also. All I need is
a meter that allows me to derive a signal strength difference from two
different antennas. There was a need to calibrate that.

Of course, I would *love* to have a decent analyzer!!

Mike, I understand that feedline radiation is an un-escapable
characteristic of an OCF dipole, caused by the asymmetric feed. Some
even claim it as a major advantage (eg Caroline Windom). Whilst no
dipole is perfect in that respect, the OCF dipole is less perfect, and
it may be worth modelling the thing to comment in your findings on the
probably magnitude of the contribution by the feedline.

Great project, look forward to follow-ups.

Walt isn't presently posting for reasons of his own.
He certainly gave me permission to quote his email. I
will ask him if he wants to defend his statements here.

> If Walt has something to say, I'm sure he will chime in.

I'm sure he will if he feels so inclined.

> Drumming up support by writing what we **think** others say or mean
> seems pretty desperate.

Those were Walt's words, not mine. (Your statement reeks of
desperation, i.e. "Please don't quote any authorities who
disagree with me.")

> All reliable measurements I've seen disagree with Cecil's theory.

Simply not true, Tom, proving once again that you don't understand
what I am saying. My "theory" explains exactly why neither you
nor W7EL could get the current at the ends of the coil to be
equal without creating a current maximum point inside the coil.

If you would just take time to understand what I am saying,
you wouldn't need to utter falsehoods about what I am saying.

The standing wave net current at each end of the coil is indeed
the same magnitude if a current maximum or current minimum point
is located inside the coil.

Walter Maxwell says: "When reflections are present, a current node
and a current loop can appear at separate points on an inductor
simultaneously." Does that sound like constant net current through
a coil? Exactly what is it about Walt's statement that you don't
understand?

> I can't believe anyone with experience in RF systems would think a
> physically small inductor (small in terms of wavelength) would have
> significantly unequal currents in the inductor or in the terminals of
> the inductor, especially any difference caused by "reflected waves".

A 75m bugcatcher coil is about 0.2% of a wavelength and so qualifies
as "physically small". The current at each end of that coil used
with an eight foot whip is nowhere near equal. I cannot believe
that anyone with experience in RF systems could utter such nonsense.

(That logic is a double-edged sword.)

I think you and others simply didn't realize that the current in a 75m mobile bugcatcher system is almost 100% a standing wave current and now you guys are desperately trying to cover up your mistake. Others have stopped responding instead of admitting their mistake. So I ask you again: How do you explain the flow of a current whose phase is unchanging (fixed at zero degrees in a thin wire dipole). Doesn't it take a rotating phasor for current to flow? That's a simple yes/no question. What do you want to bet that it goes unanswered?

Incidentally, I posted a little questionaire a couple of days ago. The response to that questionaire has been zero. Why do you reckon all the gurus are afraid to respond?

I forgot to ask you, Tom, why you trimmed out all the
technical content from my posting and whinned about
what was left? So I ask you once again:

In the graphic at: http://www.qsl.net/w5dxp/qrzgif35.gif

do you really expect anyone to believe that 0.1+ amp
is flowing into the bottom of that coil and 0.7+ amp
is flowing out of the top of the coil. If, as you say,
net standing wave current actually flows, then miracles
must be possible and the coil is creating energy.

If, OTOH, net standing wave current just stands there
then such results as reported by EZNEC are just the
facts of physics. It is the forward current and
reflected current that are doing the flowing and
their magnitudes are indeed individually equal through
the coil.

> The coil may also be thought of as a coiled-up 1/2WL element."

Cecil,

Interesting,

The complete quote from Kraus on page 744 in my copy of his 2nd edition is:

"A coil (or trap) can also act as a 180 degree phase shifter as in the collinear array of 4 in-phase lambda/2 elements in Fig. 16.30b. Here the elements present a high impedance to the coil which may be resonated without an external capacitance due to its distributed capacitance. The coil may also be though of as a coiled-up lambda/2 element."

* It is possible that Kraus edited the comment in the 3rd edition, but I don't see the word "current" in this quote. It is considered good editorial form to indicate clearly when you have altered the original wording, unless you are trying to make a point, I suppose.

* The coil in this case is self-resonant at the frequency of use. Do you use a self-resonant coil for your 80 meter bugcatcher? (Such a coil might be more appropriate for a pterodactyl catcher.) In any case, this has little to do with all of your rantings about loading coils. I suspect even at A&M they must have mentioned something about the characteristics of resonant circuits.

* You might have noticed the prominent role of capacitance. I believe that was the item that spurred this thread.

Gene, I assume you know it is common practice to insert words in
parentheses in a quotation to make the meaning clear. Such words
are understood not to be part of the quote. Since Kraus illustrated
the current, not the voltage in Figure 23-21 and earlier in figures
14-2, 14-3, and 14-4, it is rather obvious that he was talking about
a 180 degree current shift. Nowhere that I have seen does Kraus
illustrate the voltage on a standing wave antenna or talk much about
that voltage. Do you see the arrows drawn on the antenna in question?
Do you not know that an arrow drawn on a line denotes current? And
note that since all the current arrows are pointing to the right,
there is a 180 degree current phase shift in each of those phase-
shifting coils.

However, I see I should have used brackets because Kraus was already
using parentheses. I promise to do better next time.

Again, there is hardly any technical content in your reply. You have refused to respond to the questions I listed for you in an earlier posting. One wonders why you are avoiding the technical issues.

So I'll ask again. At http://www.qsl.net/w5dxp/qrzgif35.gif

is an EZNEC simulation. How do you explain the 0.1+ amp of current 'flowing' into the bottom of the coil and 0.7+ amp of current 'flowing' out of the top of the coil. How, exactly, is the coil manufacturing extra current? Hint: such a thing happens all the time in a standing wave environment because standing wave current doesn't flow. How could it possibly flow with a constant fixed zero degree phase angle?

Gene, W4SZ wrote:
"You might have noted the prominent role of capacitance."

Capacitance is one of the factors which include resistance, inductance, conductance and capacitance which determine the velocity factor and other characteristics of a transmission line or antenna. If the load at the end of this line does not match Zo, a reflection from it results.

A transmission line can`t be analyzed as a simple series circuit, because the current in the wires is not everywhere the same. Neither is the voltage. To analyze the line, each unit length must be examined.

Each unit length produces a phase lag in the current on its wires. The voltage lags too. This can be totaled and the interference between the incident and reflected waves deternined to find the voltage and current at any point on the transmission line,

Cecil,

What you are missing is the flux inside the coil links all the turns at light speed. When it does that, current appears at nearly the same instant of time (light speed over the spatial distance of the inductor) in all areas that are linked by flux.

The flux coupling also tries to equalize currents throughout every area of the coil.

Charge conservation also dictates that any current flowing into the coil has to be equalled by a like current flowing out the other terminal, less any displacement currents caused by stray capacitance (electric fields) to the outside world.

We cannot have a two terminal "black box" with confined fields that behaves any other way, standing waves or not.

The only flaws in having zero current phase shift and zero current difference are the less-than-perfect flux coupling and less-than-perfect confinement of the electric field. Any deviation from following perfect two-terminal rules are directly tied to the ratio of load impedance on the inductor to the stray capacitance to the outside world, and of course less than perfect flux linkage from end-to-end in the coil.

People can often better understand the limits when things are taken to an extreme.

Imagine a helical whip antenna. It is a very poorly constructed "loading coil". It has nearly infinite termination impedance at the open end, and very poor mutual coupling from turn to turn. The form factor is very distorted, far from being equal in diameter and length. The ratio of distributed capacitance to termination capacitance is very large, it can be nearly infinite.

A loading inductor or helical whip like this behaves nearly like an antenna.

The opposite would be a toroid, with a very compact form and almost total confinement of fields. Standing waves or not, as long as it is not near self-resonance it has evenly distributed current inside and at each terminal.

Most well-designed efficient short antennas use a loading coil having very nearly equal currents at each terminal. Current equality actually is a good way to determine a properly designed loading coil.

If you can stay on topic and we process only one point at a tme, I'm sure you will be able to learn how this works. If you see any flaw in how I just described inductor behavior, please point it out. Once we agree how an inductor works everything else will fall into place.

Yes, and that also applies to a real-world loading coil installed
in an environment of incident (forward) and reflected (backward)
waves. Why this is so difficult for some people to understand
is puzzling. All one has to do is use the superposition principle.
Analyze the forward wave, analyze the reflected wave, and superpose
the results.

I know it is not what you asked for, but a functional replacement might be a HP crystal detector that you frequently see on Ebay for less than $100. The downside is that the consequences of destroying the diode are more expensive.

Not to mention that - you might locate 1N21-R 's - which are
Reverseable, and will leave you with the pin conductors , on BOTH
ends, if you leave off the 1/4 inch cover that is swappable for the
ends! And, of the mounts I have seen (they used for power out/mixer
diode adaptors, for "C" band (6 GHz), they have a "N" male fitting
to a "BNC" output female, BUT-- they have a wire in place from the
center to the shield of the "N" end! (this for an rf choke, at 6 GHz)
which would make then useless (unless you remove that jumper, buried in
the male end , delicate surgury, inside the connector)! Lenkurt,
Farinon, and several other outfits used these in their comm equipment!
Tho, most of the plumbing I saw, had the mounts in waveguide, these
MIGHT be an option, if you can locate them-- Jim NN7K

Hi Chris,

Hence my comment about the availability being either custom design or cannibalized from 50 year old equipment.

It seems to me, that you can hold one half of the diode with an AGC fuse holder. Given that this style of diode often comes with a cartridge style mount that is removable to reveal two pin connectors (making the whole diode look like a miniature old-fashioned rolling pin for dough), you could buy two such diodes (yeah, expensive) and combine those cartridge mounts so that both ends can be captured by an AGC fuse holder.

I am not missing the flux linkage. What you are missing is the known phase lag that the current undergoes compared to the voltage. Whatever voltage phase shift you measured (60 degrees), the lagging current phase shift is likely to be more than double that value. Hint: an ideal inductor forces the current to lag the voltage by 90 degrees. If the current propagates at the speed of light, the voltage propagates much faster than the speed of light so it can lead the current. Please explain that one to us.

> The flux coupling also tries to equalize currents throughout every area
> of the coil.

A well known fact. It applies to the forward current and reflected current, not to the standing wave current which is not flowing into or out of the coil at all. There is no net charge flow in a standing wave and therefore, no net current flow. At any point on a 1/2WL thin wire dipole, the only thing happening is that the energy is migrating between the H-field and the E-field. There is zero energy flow away from that point in either direction. That's why the phase angle of the reflected current is constant and fixed at zero degrees. It is simply not flowing. What is flowing is the forward and reflected component currents which indeed to obey all the rules you have listed here.

> Charge conservation also dictates that any current flowing into the
> coil has to be equalled by a like current flowing out the other
> terminal, less any displacement currents caused by stray capacitance
> (electric fields) to the outside world.

Absolutely no argument here. Even assuming the coil is lossless, the magnitude of the forward current flowing into the coil is equal to the magnitude of the forward current flowing out of the coil. Likewise for the reflected current. So this part of your argument is somewhat irrelevant. What you seem to be missing is the phase shift in those component currents.

> We cannot have a two terminal "black box" with confined fields that
> behaves any other way, standing waves or not.

If a piece of transmission that is an appreciable percentage of a wavelength is coiled into a coil that is an appreciable percentage of a wavelength, why is it surprising to you that the coil responds somewhat like the piece of wire that it replaces? The answer is that you assumed the proof in your argument. It goes something like this:

A lumped inductance doesn't have any magnitude change or phase shift through the coil. A bugcatcher loading coil is a lumped inductance. Therefore, a bugcatcher loading coil doesn't have any magnitude change or phase shift through the coil. The first proof that you offered some months ago was that the lumped inductance modeled in EZNEC didn't show any magnitude change or phase shift. Do you see the fallacy in your thought processes? You assumed the proof in your argument and you are still falling into that logical trap. Is it any surprise that a software program shows no magnitude change or phase shift? Please open up your mind and think the unthinkable. You will be rewarded.

> The only flaws in having zero current phase shift and zero current
> difference are the less-than-perfect flux coupling and
> less-than-perfect confinement of the electric field.

There you go, assuming the proof in your argument. A lossless non-radiating transmission line doesn't even obey those rules. Why should you expect a real-world coil made from that transmission line wire to obey those rules? Before you respond with the 2-terminal Vs 4-terminal argument, please realize that a horizontal #14 wire 30 ft. above ground is considered to be a single-wire transmission line with a Z0 of around 600 ohms. Thus, a horizontal dipole is simply a lossy transmission line.

If you would like, I can quote Balanis on all of this.

> Any deviation from
> following perfect two-terminal rules are directly tied to the ratio of
> load impedance on the inductor to the stray capacitance to the outside
> world, and of course less than perfect flux linkage from end-to-end in
> the coil.

Assuming the proof again. 1/4WL apart in a lossless, non-radiating transmission line, the standing wave currents are wildly different. Why are you surprised when we take that 1/4WL of wire, wind it into a coil, and achieve a lot of the same conditions?

> If you can stay on topic and we process only one point at a tme, I'm
> sure you will be able to learn how this works.

I'm certainly game for that. We can start by agreeing that the forward current through a loading coil has the same magnitude at each end of the coil but suffers a phase shift through the coil. You measured a voltage phase shift of 60 degrees through a 100uH coil at 1 MHz. Since the current lags the voltage in a coil, the current phase shift has to have been greater than 60 degrees, maybe even 120+ degrees depending upon the Q of the coil. Tom, even I can measure the traveling wave current phase shift in a 75m bugcatcher coil so please don't insult my intelligence by asserting that a phase shift doesn't exist.

If a coil could eliminate phase shifts, Intel would be using them in
their computer busses. The truth is, a coil in a computer bus
increases the phase shift, not decreases it. So please give us a
break on that irrational concept. You have been fooled by your model.

Tom, I can't believe you have the balls to lie about such a thing
when it is so easy to prove otherwise. Your behavior is unbelievably
unethical. I simply cannot believe you are willing to go to these
lengths to satisfy that insatiable ego of yours.

W5DXP asks Walt:
And Walt, would you mind if I add just your following comments
to the thread on qrz.com and credit them to you? I trimmed out
any reference to me or Tom.

Walter Maxwell earlier wrote:
> If an inductance is in series with a line that has no reflections,
> the current will be the same at both ends of the inductor.
>
> If an inductance is in series with a line that has reflections,
> the current will NOT be the same at both ends of the inductor.
>
> Consequently, circuit analysis will not work when both forward
> and reflected currents are present in a lumped circuit.

Walter Maxwell replied to the request:
> Fine with me, Cecil, but you might also add the point about the loop
> and node appearing simultanously when reflections are present--sorta
> puts the icing on the cake.
>
> Walt

Tom, not only did Walt give me permission, he pointed out something
that I had left out.

You are being unbelievably unethical. You could have handled this
in a private email to me but you are apparently willing to drag
Walter Maxwell through the mud in order to spread your old wives'
tales. Good grief, will you stop at nothing? I'm going to have to
sign off and cool down.

NOPE!

At those heights it will be an excellent antenna for close-in work.
Close in means ~100 miles daytime and up to ~600 miles nights and evenings.

Big Endian wrote:

What's the formula for Doppler shift? Why would you think it does not apply exactly to all the spectral components of your signal? Do you think you are dealing with a nonlinear system when you combine doppler shift with a complex signal?

Cheers,
Tom

the answer is... it depends. most cheap ham style doppler direction finders with electrically rotated arrays may have trouble locking on to the doppler shift if it is modulated in some ways. modulation frequencies that cause phase shifts near the simulated rotatation frequency will be worst as they will likely be detected by the simple audio phase detector as the doppler signal and throw it off. if you use a better demodulator that is matched to the type of signal you are tracking and still can produce an output that is locked to the phase of the rotating array then it will work. this means if it is a wideband digital signal you will have to lock on to the base signal and still differentiate the rotation caused phase shift on top of it... not always an easy job.

I just asked my dog if she has a good feeling about how an inductor
behaves. She wagged her tail in affirmation. Now please explain why
feelings are important to this discussion.

> Do you agree or disagree with my post about how an inductor behaves?

I disagree with you about how an inductor behaves in a standing
wave environment. I agree with Walter Maxwell who said:

"If an inductance is in series with a line that has reflections, the
current will NOT be the same at both ends of the inductor."

Sorry about that, but Walt gave me permission to quote him. Note the
emphasis on 'NOT' in his statement. A 75m bugcatcher mobile system
is a *STANDING WAVE ANTENNA*, so no, I don't agree with you at all
as enumerated in my previous posting. Please don't ask me the same
question over and over. I am not going to change my mind until
you provid valid evidence to the contrary and so far, all you have
done is prove your ethics leave something to be desired.

Doppler shift is applicable to all frequency components of a signal.

It is a percentage change of the base frequenc[ies] as a function of the rate of closure or divergence between an observer and the originator of the signal.

So, for FM it applies to the carrier frequency at ONE doppler shifted value. It applies to the individual frequency [secondary] components as another doppler shifted component for each frequency. In practice, the doppler shifted frequenc[ies] among the secondary components are extremely small when compared to the prime frequency.

For spread spectrum, it is applicable to ALL frequencies.
For AM, it is applicable to ALL frequencies.
For SSB, it is applicable to ALL frequencies.
For CW it is applicable to ALL frequencies
For FM/NBFM/WBFM, it is applicable to ALL frequencies.
For unmodulated carriers, it is applicable to ALL frequencies.
For audio, it is applicable to ALL frequencies.
For ...., it is applicable to ALL frequencies.

Tom, I apologize profusely to everyone for losing my temper.
I regret that every time it happens but that time never seems
to be the final time. I canceled my posting made in anger. But
please note that me losing my temper has absolutely no bearing
on objective technical facts and has absolutely no effect at
all on the validity of my technical arguments. Galileo probably
lost his temper in front of the priests who placed him under
house arrest. That made absolutely no difference in the
scientific facts that he was asserting at the time.

I am presenting my thoughts in front of the internet gurus
in much the same manner as Galileo did to the priests. Hopefully,
they will listen better than the priests did and not put me under
house arrest. (But I have my Colt 45 ready just in case. :-)

Chris W., KE5GIX wrote:
"Can somone tell me where O can find the housings hor a 1n21 crystal detector so I can hook it to some coax and a directional coipler?"

From the appearance of the crystal, I`d think a fuse clip and a tube socket pin could be used to make connections.

Richard Clark had a good idea to look for ancient military surplus. These diodes were also prevalent in commercial microwave sets which are now long pbsolete.

It reminded me I have a military TS-1268/U "Crystal Rectifier Test Set" made to test these crystals in 1945. It`s been stowed away for years, but I broke it out and tested a crystal, It uses a 1.5-volt dry-cell to measure forward and reverse currents on a meter (0-1 ma). The battery was still good and the 1n23 tested OK.
It is obviously ddurable so I`m going to keep it.

Maybe Fair Radio Sales or some such surplus dealer has exactly what you want. My stock of test diodes comes in lead cylinders.

That's exactly what I intended doing, feeding a moxon rectangle in
this case, my win4nec model gives 50+0.1j.

Given the correct grade of ferrite, it should probably be ok on
UHF.

But how to to determine the effectiveness? Maybe a small bead with a
couple of turns to pick up voltage nodes on the coax feedline, with
and without the choke balun beads.

>> If an inductance is in series with a line that has reflections,
>> the current will NOT be the same at both ends of the inductor.
>>
>> Consequently, circuit analysis will not work when both forward
>> and reflected currents are present in a lumped circuit.

He agreed but suggested I also include his fourth statement which
followed the above three statements.

>> When reflections are present, a current node and a current loop
>> can appear at separate points on an inductor simultaneously.

When I went back to copy and paste bottom-up from his email
in order to include his fourth assertion, I inadvertently copied
one too many sentences at the top. It is true that I didn't have
Walt's permission to publish that extra first sentence in his email.
I regret that accidental mistake and wish I could take it back.
And of course, neither Walt nor anyone else in the universe agrees
with me 100%.

But please note that accidentally including that first sentence doesn't
change the technical content of Walt's other four assertions which should
be allowed to stand as is until further notice.

I like j-poles, made of copper pipe. Their appeal to me is their absolute ruggedness and the freedom from any counterpoise. Just last week, I looked at my oldest one (~12 yrs) and it looked good as new except for a light patina. Aluminum would be nearly dust at that age. In addition, I have developed a method of connectorizing a j-pole that is more secure than just a single pop-rivet.

On your tower, you can mount two up and one down, with the two up being the 1.25m and the 70 cm. (I think there will be the least interaction between that pair -- just a hunch.) Putting the 2m j-pole down is unlikely to hurt its pattern much; I did some informal experiments with masts near a j-pole and I had to get to less than a two-inch separation distance to affect either transmit or receive.

If I can't get 1:1 as my VSWR low point, adding a cap in series with the feed usually fixes it (100pF, or so).

You may not need all three antennas. A 2m j-pole is a reasonably good match at 70 cm, although the major 70 cm. lobe is not aimed at the horizon. There is radiation to the horizon, however, evidenced by the fact that I just raised a repeater on Palomar Mountain, about 42 miles to the north, using 0.5W into that durable 12 year-old copper j-pole, cut for 146 MHz. The antenna is only about 20 feet above the ground but I am clear of obstructions to the north, which helps. (At 60 ft, you will be clear of obstructions, too, you lucky devil.)

The up-side of using the 2m j-pole as a dual-bander is that you can dispense with the triplexer and run two cables up the mast.

The down-side of reading this far is that you now have additional choices -- not what you wanted, eh?

West,

Some thoughts:

The economics of feedline(s) might tilt the solution in favour of a
single triband antenna with LDF4-50 or better, though you will
probably want a very short flylead to the handheld. (Note that the
loss in 100' of RG213 at load VSWR=1.5 is 5dB at 70cm, whereas LDF4-50
is 1.5dB, and the loss in a 5' tail of RG58C/U under similar
conditions is 0.7dB.) If you only want to work repeaters and your path
is good enough, losses might not be an issue. (Remember though that 5W
handhelds get really hot on full power.) Is LDF4-50 overkill for a
handheld? It might be more appropriate than with a higher powered
transmitter.

If intermods are an issue (as handhelds have less than adequate front
end selectivity), do the repeaters use CTCSS... at least that helps
prevent the transceiver breaking mute all day and night. Does the
radio have a real rx attenuator that can help with intermods, to you
have sufficient rx signal strength to be able to use it?

At least you are not intending using a discone. Handhelds rarely work
well on external broad antennas (for intermod reasons), and even the
multiband antennas can be a challenge for handhelds.

Hi Mike

Since you are acknowledging the existence of 1/10th of an ohm of inductive
reactance, at UHF, you are way beyond my level of accuracy in any
measurement of effectiveness.
But, I once measured the inductance across the ferrite tube by connecting
the impedance "meter" to the exposed ends of the coax braid that was
threaded thru the center of the ferrite. Then I removed the ferrite and
repeated the test with the ferrite removed.

Roy Lewallen has an excellant paper written to show how to properly evaluate baluns. I have the paper saved and will be happy to share it with you. It is almost a *must read* since it is so thouough and informative.

Chris,

If it's exactly what you're looking for, I have a hand full of these things. It's a Sage 1021H adapter and has a front end that looks like a UG 21 and a BNC on the rear. The BNC unscrews and you install the 1N21 like a .22 round , and screw it back together. It's not a tiny assembly and measures 62mm in length (just shy of 2.5 inches).

I found it listed on line at A-Comm Electronics and they say it's good to 12.4 kmc.

If it's something you really could use, I could send you a couple at a fair price.

But I'm surprised that anyone nowdays would be using a full sized type N connector for anything other than moderate powered transmitting.

John

To give you 10% resolution will require it have its local oscillator
accurate (and stable) to one part in 100 Billion (of course, same goes
for the source). Hmm, maybe Bang & Olufson....

Laser interferometry would be simpler, and probably cheaper too.

Hi Mike,

Good start, keep it simple. This presumes you have the material, but
don't know its type (s/b #43 or #64):

Take a short transmission line from your rig;
pass the center conductor through ONE bead;
and bring it back and short it to the shield;
transmit on the 5W range for as long as it takes to read SWR.

You should get a reading of roughly 1.3:1 to 2:1 for the right
material - and - depending on how long you held down the transmit, it
should get toasty warm to blistering hot.

How much dispersion can you tolerate? "Significance" is an emotional
measure (which is to say it isn't a measure at all). If you cannot
quantify what you mean by this, no one can offer how significant it
is. I've a career of measuring very small differences out to 12
places. What was significant to me was a matter of utter indifference
to 99.999999% of the population - if that many.

Then we can't go further with this Cecil, unless you can accurately explain WHY the behavior of an inductor changes when it is in an antenna, rather than in some other system where impedances are the same or very similar. It seems that Ian, Reg, Roy, and several others including myself all believe an inductor works the same way. If you convince one of us we are in error the others will surely follow!

If you refuse to discuss the behavior or electrical characteristics of the component you are talking about, there really isn't anything we can talk about. In that case I suggest you leave my name out of things, and I'll do the same for you.

When you are ready to talk about the root problem, I'll try to be here.

And also, if the inductively loaded antenna is designed by the "antenna as transmission line" method (as used by Boyer and ON4UN for example) it clearly shows that the loading inductance is simply there to cancel the net capacitive reactance - in other words, it behaves in exactly the same way as you would in any other circuit.

The irony is that Boyer *does* use the concept of reflected traveling waves in his basic explanation of how monopole antennas work. The difference is that he understood how to do it without tying himself in knots.

'Antenna Transmission Line Analog: a key to understanding antennas' by Joseph M Boyer (W6UYH, SK 1988). Ham Radio, April 1977 and May 1977.

>If you

Slip of the fingers there, Tom - there aren't any "followers" in that particular company. We are all fiercely independent-minded individuals, absolutely determined to do our own thinking and to get it right.

It is true that we agree on a lot of things, but there's only one reason for that: because physical reality is the same in Oregon, England and Scotland as it is in Georgia. There is a very high probability that it's the same in Texas too.

same way as you would in any other circuit.

The irony is that Boyer *does* use the concept of reflected traveling
waves in his basic explanation of how monopole antennas work. The
difference is that he understood how to do it without tying himself in
knots.>>

I received an email from someone (an attempted reply mail bounced) who
thinks his mobile antenna is "90-degree resonant". The the upper
portion of the antenna is physically 5 degrees long, the lower section
10 degrees, and the loading coil placed between the two about 1 degree
long. He has tied himself in a knot picturing the system as being
"90-degree" resonant, and thinking the inductor must make up the
missing 74 degrees of antenna height.

He also, as many people do, visualizes an inductror model where current
winds its way through the copper from end to end. His exact words
being: "Also, in colis(sic) of significant wire length the propagation
time of current in the wire is still approximately 1 E-9
seconds/foot."

These are the very conceptual problems I was trying to address at:
http://www.w8ji.com/mobile_and_loaded_antenna.htm

Without a detailed and correct understanding of how both inductors and
electrically short antennas behave, it's easy to go down the wrong
path.

Compounding the problem are incorrect measurement methods. One person
placed a link over a long solenoid coil and incorrectly assumed that
link would measure current in one small area of the coil, another took
off with that flawed measurement and revised his whole refelected wave
analysis to make the current maximum in the center of the loading
inductor!

It would be nice to clean this all up, but it will only happen if every
steps back and looks at the system one small step at a time. It seems
some have reached an unbendable conclusion without even understanding

how an inductor works. It is critical to understand what goes on inside an inductor if we are going to talk about current inside the component.

It think that is the root of the disagreement, and until it becomes the focal point the myths about standing waves, a 10 degree tall antenna being 90 degrees, and current flowing in two directions at the same instant of time at one point in the system will continue.

We need to talk about the inductor, or this will go nowhere and in another three years pop right back up.

Case #1 two 50 ohms in parallel plus a transmission line > 25 to 100 ohms and everything in between [VSWR = 2:1]. If there are no transmission line effects [very short line] then 25 ohms.

Case #2 one 50 ohm = 50 ohms including transmission line effects.

w8ji@akorn.net wrote:
> Then we can't go further with this Cecil, ...

That's simply not true. We can take this discussion to its logical conclusion if you are not afraid to continue it in logical order at a logical starting point.

Starting with coils is like looking for your keys under the street light, instead of where you lost them, because that's where the light is better.

Coil theory is not the problem. Standing wave current theory is the problem. Let's discuss the problem.

> If you refuse to discuss the behavior or electrical characteristics of
> the component you are talking about, there really isn't anything we can
> talk about.

I'm not refusing to discuss anything as long as it is taken in logical order. Our disagreement extends much farther back into fundamental technical principles than just the subject of coil function. We actually may have no technical disagreement about coils. I believe our basic disagreement involves standing wave current, not coils, so standing wave current should be the topic of this initial discussion. For that, we need to first agree on the 1/2WL thin wire model of a dipole.

Let's see what we can agree on. Can we agree on the following pertaining to a 1/2 wavelength thin wire dipole?

The net current in a standing wave antenna is a standing wave. The net current displayed by EZNEC for a standing wave antenna is a standing wave. The net standing wave current is the phasor sum of the forward current traveling wave and the reflected current traveling wave. The principle of superposition applies to the two component waves. If we superpose the forward current traveling wave and the reflected current traveling wave, we obtain the net standing wave current.

Let's take for instance, that 1/2WL thin wire dipole. The standing wave current distribution and phase appears in Figure 14-2 in Kraus and Figures 1.15 and 4.8 in Balanis. If the current at the feedpoint is 1 amp, the net standing wave current equals cosine(x) where 'x' is the distance in degrees away from the feedpoint.

This topic of discussion will most likely reveal that our fundamental point of disagreement is standing wave current and not coils at all.

So which points above do you agree/disagree with?

References to Kraus are from "Antennas for All Applications",
Kraus and Marhefka, 3rd edition.

References to Balanis are from "Antenna Theory", Balanis,
2nd edition.

If that is true, you guys shouldn't have any difficulty proving me wrong
and sending me back to the woodshed once and for all. If the above is not
entirely true, please don't put me under house arrest until I present the
truth as I see it. And certainly, call me on anything that is wrong.

If you will keep listening with an open mind, I think I can show you
that the words, "clearly", "simply", and "exactly", in your above
statement are not entirely correct.
--
Ian, no one has explained the antenna currents reported by EZNEC at:

http://www.qsl.net/w5dxp/qrzgif35.gif

How can 0.1+ amp of current be 'flowing' into the bottom of the coil
and 0.7+ amp of current be 'flowing' out of the top of the coil. It's
been days now and no one has offered an explanation.

Here's a question for you, Tom. Assume for reference that the forward current phase is at 90 deg and the reflected current phase is at -90 deg at the tip of the antenna and then backtrack the two phasors to the feedpoint. The phasor currents are known to rotate in opposite directions. The question for you is: What is the phase of the forward current originating at the feedpoint? What is the phase of the reflected current returning to the feedpoint?

Seems you are trying to tell us that the phase of the forward current at the feedpoint is at a phase angle of 90-16 = 74 degrees and the phase of the reflected current is -90+16 = -74 degrees at the feedpoint since, as you say, the antenna is 16 degrees long.

Assuming angle F is the feedpoint phase of the forward current and angle R is the feedpoint phase of the reflected current:

We know that net current at the feedpoint is Ifor*cos(F) + Iref*cos(R)

According to your theory the net current would be

Ifeedpoint = Ifor*cos(74) + Iref*cos(-74) = .028(Ifor+Iref)

Since the feedpoint impedance is inversely proportional to the feedpoint current, the feedpoint impedance for your loaded vertical would be a lot higher than the feedpoint impedance for a 1/4WL vertical but we know it actually goes in the opposite direction. How do you resolve that contradiction?

> He also, as many people do, visualizes an inductror model where current
> winds its way through the copper from end to end. His exact words
> being: "Also, in colis(sic) of significant wire length the propagation
> time of current in the wire is still approximately 1 E-9
> seconds/foot."

For an ideal inductance, the voltage propagates through the coil at the speed of light. The current lags the voltage by as much as 90 degrees in an ideal inductance.

For an ideal capacitance, the current propagates through the coil
at the speed of light. The voltage lags the current by as much as
90 degrees in an ideal capacitance.

> It seems
> some have reached an unbendable conclusion without even understanding
> how an inductor works.

It is not your understanding of how an inductor works that is the
problem. It is your misunderstand of how standing wave current
works that is the problem. Let's discuss the problem on the other
thread in progress.

> We need to talk about the inductor, or this will go nowhere and in
> another three years pop right back up.

You are looking for your keys under the street lamp instead of where
you lost them, because the light is better. The inductor is NOT the
problem. Your misunderstanding of standing waves is the problem.

You fully understand how a coil works in the presence of a traveling
wave. You do not understand how a coil works in the presence of
standing waves, not because you lack understanding of a coil, but
because you lack understanding of standing wave current. If you
keep avoiding your area of misunderstanding, this will go nowhere.

Okay. Perhaps I might better characterize my experiment as a comparison of a vertical and an OCF dipole of indeterminate vertical vs horizontal performance. I was under the impression from the designers of this flavor of dipole that they were not radiating from the feedline unless you wanted that "feature". In that case you would feed the antenna with balanced line. Certainly the antenna doesn't seem to be radiating RF from anywhere but the antenna bits.

p.s. forgive the spelling, I am using a beta of Thunderbird for my newsgroups, and it seems to have a few quirks that make it hard to see what I have written!!

It certainly seems you have reached an unbendable conclusion without even understanding how an inductor works in a standing wave environment. The following reference, emailed to me by a kind reader of this newsgroup, says exactly what I have been trying to say. I propose that a 75m bugcatcher loading coil is a "velocity inhibited slow-wave helical transmission line resonator". The only difference between it and a 1/4WL resonant Tesla coil is the radiating part of the antenna. I'll quote a few excerpts.

http://www.ttr.com/corum/index.htm

[begin quote]
Tesla Coils and the Failure of Lumped-Element Circuit Theory
by Kenneth L. Corum and James F. Corum, Ph.D.
ï¿½ 1999 by K.L. Corum and J.F. Corum

In all of those [lumped] circuit models the current is analytically presupposed to be uniformly distributed along the wire in the coil ... There are no standing waves on a lumped element circuit component.

However, a true Tesla coil (circa 1894) is a velocity inhibited slow-wave helical transmission line resonator: ... one needs transmission line analysis (or Maxwell's equations) to model these electrically distributed structures. Lumped circuit theory fails because it's a theory whose presuppositions are inadequate. Every EE in the world was warned of this in their first sophomore circuits course.

This phenomenon is decisive. It occurs only on distributed resonators: it is impossible with any lumped circuit element! (The current has the same value at every point along a lumped-element.) To understand what is happening, consider a cylindrical helical coil of height H. The base is always forced to be a voltage node (it's grounded). The top is always a relative voltage loop at the odd quarter-wave resonances and a voltage node at the even (half-wave) resonances. These boundary conditions constrain the mode patterns on the structure (called spatial harmonics). We assert that velocity inhibited partially coherent forward and reflected RF traveling waves form interference patterns on the coil.
[end quote]

"Lumped circuit theory fails because it's a theory whose presuppositions are inadequate." Seems some EEs have forgotten that sophmore year warning.

Using lumped circuit theory in the presence of standing waves is a form of "assuming the proof" or "begging the question" and is simply invalid.

Quoting relevant material from Balanis: "The current and voltage distributions on open-ended wire antennas are similar to the standing wave patterns on open-ended transmission lines. ... Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave currents If and Ib ..."

Source record: 63608

Ken,

I guess that you are using the T-connector simply as an elbow? If this is the case, and you put a 50 ohm load on one leg, you should leave the other leg *open* to make the impedance be about 50 ohms. The T-connector will give you a little bit of capacitance due to the concentric conductors on the unused leg, but it will make little to no difference until you hit UHF or so.

If you put 50 ohms on one leg and a 50 ohm load on the other, Amos's post will apply. The impedance seen by the transmitter will depend on the length of transmission line between the T and your transmitter. This is because the line between the T and your transmitter is no longer properly terminated at the T end.

With very short transmission lines, the situation is just like parallel resistors. This means that the two loads on the T will share the power.

This is good for things like phased yagis, but you wouldn't want to hook an antenna to one port and a dummy to another...

Dang Reg, I forgot to post the quote from that web page. Here it is:

"Lumped element representations for coils require that the current
is uniformly distributed along the coil - no wave interference and
no standing waves can be present on lumped elements."

Therefore, lumped element representations for coil CANNOT be
used to analyze standing wave antennas. I wasn't the first
to say that. Using a lumped element representation for a
coil in a standing wave environment is "assuming the proof".

Here's more information along those same lines.

There is one typo in that statement: I posted it part-way through
changing from "In other words, you use the inductance in exactly the
same way as you would in any other circuit" to "In other words, it [the
inductance] behaves in exactly the same way as it does in any other
circuit". I stand by both of those statements.

It's because you modeled a real-life coil, whose length and diameter are
each a significant fraction of the size of the whole antenna. Nobody
disputes that the currents at the two ends of a real-life coil are going
to be different... but the reason is because of its other properties
besides pure inductance.

You are hung up on something far more fundamental. You are
misrepresenting the fundamental electrical properties of inductance to
make them fit your theory.

That is only true if you say it about pure inductance.

But a "coil" is a real-life component that has other properties like physical size, number of turns, self-capacitance and leakage inductance. A coil interacts electromagnetically with the circuit in which it finds itself, so it doesn't always behave in the same way. But pure inductance does.

The difference between inductANCE and an inductOR - a real-life coil - is not just playing with words.

There is a reason for having those two different words... and that reason is the key to this whole debate.

Reg Edwards wrote:
"Has it ever occurred to you guys that a coil is a coil however it is used and always behaves in the same way?"

Yes! But when it is part of an antenna system, the system imposes energy upon the coil in ways which the coil does not control. "The system is the solution", AT&T used to say.

John D. Kraus writes on page 176 of his 1950 edition of "Antennas":
"The term transmission mode is used to describe the manner in which an electromagnetic wave is propagated along an infinite helix (that`s a coil, right?) as though the helix constituted an infinite transmission line or wave guide."

Wave guides and transmission lines are subject to reflections. These produce the standing wave patterns exhibited in many text books. Kraus uses the helix very generally. To him it can collapse to a single loop or be stretched to a straight wire.

When a "normal mode" helix (coil) is used as part of a antenna system, It radiates normal to the axis of the coil, similar to the manner it would were it stretched out to a straight wire. A reflection within the antenna system would return energy toward the generator, similar to the manner it would with straight wires. The same sort of interaction between incident and reflected waves must occur. There is no other way. These produce variatiations in both current and voltage in a periodic manner along the helix as described for transmission lines which should be familiar to all.

The whole section of helical antennas in Kraus is interesting. Kraus is the inventor of the Axial mode helical antenna. I think he tells the story in his 3rd edition of how he went home and wound one up and tested it after being told by an expert of the times that such an antenna was impossible.

Best regards, Richard Harrison, KB5WZI

I agree with Cecil.

An Inductor in a DC circuit under transient conditions has a classic L/R response.

An inductor in a AC power line [60 Hz] acts as a classic inductor.

An inductor in a LF antenna system acts as a classic inductor when the physical AND electrical dimensions are very small compared to a wavelength.

An Inductor in a HF shortened antenna does NOT act like a classic inductor. It is a significant portion of the HF circuit and must be treated as such.

My 60 meter mobile antenna is 90 degrees long, 1/4 wavelength resonant at 18 +j0 ohms [MFJ analyzer]. It is 10 degrees long from feedpoint to base of coil. Current into the coil is 98% of feedpoint current [cos 10 degrees]. The antenna is 5 degrees long from top of coil to top of antenna. The current at the top of coil calculates to 9% of feed current [sin 5 degrees].

Conclusion: the coil, at 75 degrees of the circuit, has to be treated differently from DC or LF models.

Ian, old boy, you are no better than the rest of the gaggle !

There's not one of the clever buggers who can design a coil-loaded
whip for a given frequency using a pencil, paper and a pocket
calculator.

They have to copy an already existing, pre-tested, model after
searching through the antenna comics.

Reg.

Too bad you are standing by false statements. :-)

Quoting: http://www.ttr.com/corum/index.htm

"... one needs transmission line
analysis (or Maxwell's equations) to model these electrically
distributed structures. Lumped circuit theory fails because it's
a theory whose presuppositions are inadequate. Every EE in the
world was warned of this in their first sophomore circuits course."

Seems you weren't listening that day, Ian.

"Lumped element representations for coils require
that the current is uniformly distributed along the coil - no wave
interference and no standing waves can be present on lumped elements."

> It's because you modeled a real-life coil, whose length and diameter are
> each a significant fraction of the size of the whole antenna.

A 75m bugcatcher coil is a real-life coil, Ian. Contrary to what
W8JI asserts, it is a significant fraction of the size of the
whole antenna. It uses 42 feet of wire, for goodness sake.

> You are hung up on something far more fundamental. You are
> misrepresenting the fundamental electrical properties of inductance to
> make them fit your theory.

I am using distributed network theory known to work in a standing
wave environment. You are using lumped element theory known to
fail in a standing wave environment. A 75m bugcatcher mobile
antenna is a standing wave environment. So exactly who is
"misrepresenting the fundamental electrical properties of
inductance to make them fit his theory"?

Amos Keag wrote:
> I agree with Cecil.

Good to hear.

> Conclusion: the coil, at 75 degrees of the circuit, has to be treated
> differently from DC or LF models.

Yes, I just ran an experiment that would support that statement.

My 75m bugcatcher coil is mounted on a one foot bottom section
on my pickup. I'm sorry but I can't fasten the coil directly
to the mount for reasons of clearance. But one foot at 75m is
only about 1.5 degrees so let's call it negligible.

I have one of those 12 foot telescoping whips from MFJ. It's
great for portable operation from my pickup. It is adjustable
from 2 feet to 12 feet. The first measurement I made was with
no whip at all, just the bugcatcher sitting on top of a one
foot bottom section. I used an MFJ-259B for the measurements
connected through a two foot W2DU choke. Here are the results.

resonant
Stinger frequency
0' 6.7 MHz
2' 5.1 MHz
4' 4.3 MHz
6' 3.8 MHz
8' 3.5 MHz
10' 3.2 MHz
12' 3.0 MHz

It's more than obvious that with a stinger length of 0', the
coil is very close to 1/4WL and is NOT a lumped inductance.
The current at the top of the coil is obviously zero.

So moving down the frequency in 2' increments, exactly when
does a coil made with 42 feet of wire become a lumped inductance
in the presence of standing waves?
http://www.ttr.com/corum/index.htm says never.

When I get my MFJ current meter, I will actually measure the
current at the top and bottom of the coil.

Unfortunately, even if the designers don't intend the feedline to radiate, it's very difficult to avoid. A single balun at the feedpoint is very likely not enough to prevent it.

In that case you would feed the
> antenna with balanced line.

That would make no difference at all in determining whether or not the line would radiate.

Certainly the antenna doesn't seem to be
> radiating RF from anywhere but the antenna bits.

The amount of feedline common mode current and therefore radiation will vary from band to band, probably a great deal. It's easy enough to make up a simple current probe with a clamp-on core and make quantitative measurements if you're interested. They've been described on this newsgroup several times.

Not necessarily either.

The T connects the branches in parallel, so if you have a 50+j0 load
and any length of 50 ohm coax connected to each of two branches, the
impedance at the T is 25 ohms. If you connect to T to something else
(eg a transmitter) with 50 ohm coax, the SWR on that section will
result in impedance transformation that depends on the coax (vf),
frequency, and length. For example, if you had 3m of RG58C/U at 7MHz,
the impedance looking into the cable would be 36+j24.

You can solve the transmission line transformation with the calculator
at http://www.vk1od.net/tl/tllce.php .

>If one leg is not being used, what should be put there (if anything)
>for the transmitter to see 50 ohms if the impedance of the other leg
>is 50 ohms?

You know the answer to that now, the branches of the T are in
parallel, leave one branch open circuit.

Hi Jim,

It is an array of co-planar, parallel monopoles driven at the same,
common point. The size of each in the array is different spanning
from short to long such that at least one is resonant within a wide
band of frequencies.

Two of these hung in the air in dipole fashion become the skeletal
version of the Bowtie antenna.

When the fan of wires are formed into an equal sized array in a circle
(with their far ends attached in a loop); you have a conical antenna
(cone shaped, driven at the pointy end against ground).

All such designs have a reputation for being widebanded, but basically
only as useful as a quarterwave monopole (at any of the resonant
frequencies). For the conical versions, they can resonate over a
considerably wide band, and in fact up to 6 to 10X of the first
resonance. Unfortunately, having a resonance this high does not mean
it is useful. This is because the antenna will be so very long at
that extreme harmonic that most of its radiation will be directed
along its length rather than broadside. This may be an unintended
consequence. The fan design, on the other hand, will have a short
length element that will provide the expected pattern.

> it will make all that much difference if any?

There will be a marked improvement in the low angle performance in the direction off the ends of the antenna (the flattop is very poor at this). This will come at the expense of a sight loss (about .8db) off the pattern's top (where you can most afford it). You will also experience a slight deterioration in the SWR (based on 50 ohm coax) from about 1.34 to 2.05, easily managed by any tuner, including those built into many radios. You will also find that you need to shorten the antenna very slightly to maintain the same resonant frequency.

This won't make it into a superior DX antenna but it may allow you to hear things you missed before. Basically, Bob Heinlein was right. There ain't any such thing as a free lunch.

There is a small dispersion caused by the modulation scheme. The
modulating frequencies are slightly different from the carrier frequency
and therefore have slightly different doppler shift.

Restated: the Doppler shift on a 144.500 MHz carrier is different from
the Doppler shift on a 15 KHZ FM signal. How much? That's an exercise
for the student ... so sez my Prof!!

The doppler shift of 144.500 MHz is different from the doppler shift of
a 144.515 MHz sub carrier. If the FM moves the sub carrier doppler moves.

OK, Amos, I see what you wrote as a set of changes of frequency, all in the same proportion, exactly as I'd expect from the Doppler formulas I've seen, including relativistic ones. But how does that relate to dispersion? Perhaps kb7qhc will offer us a definition of dispersion...

Doppler does. However, you should follow the nature of the thread in
that it is discussing a spectrum of emission, not just one frequency.
When you have more than one associated frequency, and the source(s)
are in a moving reference plane, these frequencies are all shifted by
the proportion of their frequency in relation to their speed. This
gives rise to corruption of waveshape in modulations - dispersion.

==========

Dear Cecil, you know as well as I do, that pruning the coil is not DESIGN. It is a procedure done by people who are floundering about in the dark. Not by supposedly professionally qualified engineers who are participating in this discussion.

Anybody, even a CB-er, can make an antenna with the top of the whip a mile long and then severely prune it until the antenna resonates at the pre-determined frequency, following a score of attempts to use coils of different dimensions and numbers of turns. But even the experimenting CB-er has to understand what he is doing.

Not so the so-called professionals.

It appears from this discussion the university-educated Ph.D professionals are the ones who are floundering about in the dark.

Silly old-wives indeed.

As I have said before, the standards of education in Western schools and universities are dropping to bits. Chinese, Japanese, Korean, Iraqian, Iranian, Afganistan, Indian, Pakistan, Vietnam and Indianesian school kids, not forgetting the half-starved sewer-rats of Rio-de-Janerio, are better at arithmetic. And, what is more important, what stems from it!

If you are interested I am on Spanish, Valencia Red tonight. It is supposed to minimise cholesterol in the blood stream.

Your old pal, Reg.

Radiation from feedlines is grossly exaggerated.

For many purposes, practically it does not occur.

When discussing the importance of such radiation one should always
crudely estimate its level relative to transmitter or radiated power.

If you don't know what its level is then you don't know what you are
waffling about.

Reg.

You can probably get lots of comments from users of Doppler DF antenna systems about the performance to be expected. (There's a "fox hunting" email list that could get you into a group with lots of direction-finding experience quickly.) Of course, since indicated direction depends on the detected phase of the received Doppler-derived FM modulation, relative to the antenna "rotation," it is important to use a detection path that maintains a very stable phase shift. It's generally useful in practice to have a very narrow filter on the Doppler-derived FM, so that other modulation on the signal does not interfere with your detection. You can do that with switched-capacitor "analog" filters, or with digital filters, locked to the antenna-switching subsystem. Expect multipath to mess up your indication just as it can with any other direction-finding technique. Many practical factors affect how well your antenna system will work. Beware of the mutual impedance among all the antenna elements: you will probably want to insure that elements which are de-selected are non-resonant. If you don't need very fast indication of bearing, you may do better with a rotating directional antenna, ESPECIALLY in terms of minimum detectable signal. If you want to know just how well this Doppler DF scheme is going to work with a particular signal (with perhaps broadband complex modulation), I'd suggest that it's a pretty easy experiment to set up, either with the antenna and receiver you plan to use, or even by generating a version of the source signal with FM added. I have this vision of you trying to detect something that looks like 5MHz wide random noise modulated by a 50kHz-deviation FM, using a receiver with a 50kHz or 100kHz bandwidth, and perhaps being very disappointed in performance.

Finally, why didn't you indicate in your original posting that it was a particular direction-finding application that you were interested in? That probably would have gotten to the point a bit quicker.

Cheers,
Tom

OK, so all wavelengths shift by the same ratio. In what way does that change the "waveshape in modulations," other than to simply change the time scale by that same ratio?

Or--does Doppler shift (alone) give rise to different propagation velocities at different frequencies? Does Doppler shift change an impulse to a chirp (or the right chirp to an impulse)?

Yes, in fact they do. I mistakenly ascribed a disproportionality to
the relation of the doppler sidebands and the doppler carrier.

Net answer, no dispersion.

Thanks, Richard. I'd have been happy to learn that indeed Doppler shift does lead to dispersion -- "any day I learn something new is a good day." But coming to agreement was also good. Now, for the next part of the story, Doppler shift _in_combination_with_ multipath indeed does lead to dispersion, I believe. That's why I was careful in my original question to say, "Doppler alone?" See for example http://www.eleceng.adelaide.edu.au/seminars/2005/postgrad/Yu05.html. I get the impression that Ms. Yu is a pretty bright young woman.

what are you mumbling about richard? doppler direction finders operate at audio frequencies and since the detector and switching system operate from the same clock they are perfectly accurate... at least as well as you can calibrate the phase reference between the demodulator and clock.

Hi Tom,

I'd gotten it in my mind that the higher sideband would have increased
more in relation to the carrier than the lower sideband would have (or
versa vice) hence dispersion. Scribbling out the math in response to
your questions resolved that error.

Hi Dave,

Look at the question again asking for an "FM" receiver. This would require the action of the discriminator which operates relative to the LO. Any frequency offset would be a bias, not an audio frequency. There are two sources in this question, the doppler transmitter, and the doppler detector. This requires coherence. The magnitude of the doppler shift has been described all over the map without a strict correlation to the speeds (or applications) involved. When discussion devolves to FM detection of a base frequency of 2.5GHz shifting KHz (6 orders of magnitude), the necessary components (for coherence of the whole system) demand a rather strict requirement for stability and accuracy for any suitable resolution.

And, of course, some doppler applications can do it with far better economy - but that wasn't asked for.

Originally I requested a source for various length of cables with SMA Male on one end to plug into a HT (Kenwood TH-F6A) and the other end a PL-259. Lengthy and comprehensive treads soon made me realize that the PL-259 would be ill advised especially at UHF & higher. So I found some ready made cables with SMA and N connectors. The only problem (if it's really a problem) is those skinny cables they come in. Some claim that they are 50 ohms, another RG-174. I don't know the other types. Do you think it will be alright to use those narrow cables from my HT to an amplifier to my monitoring meter and then use regular RG 8 to the base antenna? Will those skinny cables present some kind of mismatch. You know it's almost impossible to solder a SMA connector to an RG 8. Thoughts, please? Thank you.

Cordially,

I don't know how you can reach that conclusion except by guessing.

The inductor has some effective equivalent series impedance that
includes resistance, reactance, and distributed capacitance.

I can easily build an inductor for your antenna that tunes the antenna
to resonance and when the top-whip is removed makes the lowest resonant
many times higher than 75 degrees plus 10 degrees at 60 meters would
appear.

On the other hand I can probably, given enough time, build an inductor
that might mislead us into thinking the coil inserted in the antenna
acts like it is about 75 degrees long.

Thinking the inductor or loading coil represents 60 degrees of
electrical length is EXACTLY where the big myth is at, and it can
easily be proven to be a myth!

Hmm ... The capacitance of a short vertical monopole above a conducting plane is a straightforward EM problem [Em 101].

Hmm ... Resonance requires a series inductance where L is proportional to N^2 times D^2. [Circuits 101]

Value of L can be adjusted using transmission line models for location along the monopole. The Zo of the monopole is proportional to the ln(len/dia minus a constant). [Antennas 101]

Given a little time to review the particulars and refresh 60+ years of separation from EM 101 I think the method would work.

But, I don't have a calculator. Would my old Pickett do?

Does this mean I don't qualify as a "clever bugger"?

Richard,

Doppler DF systems like mazerom is thinking about work by rotating a virtual antenna in a circle -- by successively selecting one antenna at a time from a set of antennas around a circle. (He finally got around to saying that in the other thread...) The effect is to ADD an FM modulation to whatever signal you're receiving. If the signal happens to be a continuous carrier, then you end up receiving a signal with just your antenna's FM modulation. If the transmitted signal was FM to begin with, your FM adds in. If it was an AM signal with carrier, you're still good to go. But if the signal looks like random noise--does FM modulated random noise not still look like random noise?

If you have reasonably clean FM to demodulate, then you just need to calibrate out the (audio) phase shifts of your detector, including whatever filtering you use to extract just the modulation your antenna put on the signal. Then you compare the phase of that detected modulation with the phase of the antenna effective rotation to get bearing. This is similar, in a sense, to how VOR works to give a _receiver_ in an airplane the bearing that receiver is from the VOR transmitter: the VOR effectively rotates a directional antenna very quickly so that the receiver sees an AM signal: max envelope when the directional transmission "points at" that receiver. But the VOR transmitter ALSO is FM modulated. So all receivers tuned to that VOR get the same FM phase reference, but the phase of the AM is different at each receiver depending on its bearing relative to the transmitter. In the Doppler DF, the reference phase is the antenna rotation, which you are controlling, and then the FM phase relative to that depends on the bearing of the arriving signal. In your receiver system, you'll want to use a very narrow filter to reject other modulation, and the trick then is to make the phase shift in that filter be very constant at the frequency of interest. A switched-capacitor (commutating-capacitor) filter will do that, if the commutation is driven synchronously with the antenna switching. But you can also do it with a digital filter which samples at a rate that's synchronous with the antenna switching.

There's an article in QST -- for May, 1978 if I'm remembering correctly -- that describes it, along with plans for constructing such a beast for 2 meters. Anyone want mine? I tried to give it away a couple years ago, but no takers. Worked OK last time I used it.

Cheers,
Tom

>RG-174.

RG-174 is a 50-ohm cable, just over 1/10" in diameter. It's a decent
choice for HT-to-whatever pigtails, at long as the length isn't so
great that losses become unacceptable.

> I don't know the other types. Do you think it will be alright to use
>those narrow cables from my HT to an amplifier to my monitoring meter and
>then use regular RG 8 to the base antenna?

Almost certainly for short lengths. I wouldn't use it for long runs.

The attenuation per 100' of RG-174 is around 13 dB at 146 MHz, and
about twice that at 440. Thus, at 440, 10' of the cable would lose
you around 2.5 dB, or less than 1/2 of an S-unit at the conventional
calibration. This loss would occur for both transmission and reception.

There are other cables of this size which are less lossy - LMR-100A
has approximately half as much signal loss per foot.

Both RG-174 and LMR-100A have solid center conductors, and might not
stand up to a very large number of flexing cycles. A cable of similar
size with a multistrand center conductor might live longer.

> Will those skinny cables present
>some kind of mismatch.

Not unless the manufacture is seriously botched (e.g. cable not
soldered to connector correctly). They're the same impedance as RG-8,
but are a lot more lossy.

> You know it's almost impossible to solder a SMA
>connector to an RG 8. Thoughts, please? Thank you.

Go for it. A pigtail of anywhere from 18" to a few feet should act as
a perfectly acceptable strain-relief for your HT's SMA connector, and
even at 440 its loss should be low enough that you'd be unlikely to
notice it.

Source record: 63553

So long as your runs are short, there should be no problem. I assume your HT expects to see something reasonably close to a 50 ohm load, and using 50 ohm coax for your connections makes perfect sense in that case. Small coax in general has higher loss than large coax. For a 100 foot run, that might be a problem. For RG-174-type cable at about 25dB per 100 feet at 450MHz, 100 feet would be pretty awful. But four feet is about 1dB, which you might notice but would be a fraction of the contribution of, say, 100 feet of RG-8-type cable at maybe 4dB. So, how long a "skinny cable" are you thinking of, and how long is your RG-8 run in comparison?

Cheers,
Tom

Al,

I've had many real open wire lines, including one over 1000 feet long.

As Clark pointed out, at extermel high voltage levels a sharp bend can
cause corona problems. In critical systems like video it can cause
impedance bumps that might create faint ghosts in the picture. It make
cause impedance to change slightly.

Sharp bends make no noticable difference at all for amateur
applications, other than weakening the wire if it is a stiff solid wire
like copperweld.

I would never give a moments worry about it.

Well then do it, Tom. But you are not allowed to use the
lumped circuit model. You must use the distributed
network model (or Maxwell's equations). I think the
distributed network model proves otherwise. Could be
you are the one spreading myths after using an invalid
model.

There's just no getting around it. The forward current
undergoes approximately a 90 degree phase shift from
the feedpoint to the end of a 75m mobile bugcatcher
antenna. It is reflected there (180 degree phase
shift) and becomes reflected current which undergoes
approximately a 90 degree phase shift from the tip
of the antenna back to the feedpoint. So from the
start of the forward current wave to the return of
the reflected current wave there is approximately
a 360 degree shift in order to put the forward current
and reflected current in phase so they can superpose
constructively. If the straight element part of the
antenna is 12 degrees, we can account for
12 + 180 + 12 = 204 degrees without the coil. The
coil is the only other thing in the whole system.
Where does the other 78+78=156 degrees of total phase
shift come from if not from the coil? I've explained
all of this to you many times. Might be a good time
to start listening.

You can prove this for yourself. Using current probes
and your o'scope you can measure the traveling wave
phase shift through a loading coil. That figure is
approximately the electrical length that is replaced
by the coil when it is installed in the antenna.

?? The RG-174 I know has stranded copper-clad steel center conductor,
so it's pretty strong but not solid. Roy Lewallen pointed out a number
of years ago, in this group I think it was, that because the copper
cladding is so thin (about one mil) on the strands, over the lower
frequencies of the HF band and below, the center conductor RF
resistance is nearly constant, and the attenuation flattens out at
those low RF frequencies as a result.

Tom, W8JI wrote:
"Thinking the inductor or loading coil represents 60 degrees of electrical length is EXACTLY where the big myth is at and it can easily be proven to be a myth!"

A vertical antenna is often driven against a reflecting ground system. It is desirable that it be self resonant at nearly 1/4-wavelength (90-degrees), in many instances, to eliminate reactive impedance to current into the antenna, avoid loading coil loss, and avoid bandwidth limitation which comes with high-Q coils. Even with its drawbacks, a base loading coil is often the practical way to resonate a too-short antenna.

Suppose the vertical is only 2/3 the height needed for self resonance, or 60-degrees high. The loading coil must replace about 30-degrees of missing antenna to bring the vertical to resonance.

30-degrees is not an inductance value. An inductor is impure because it has resistance and capacitance in addition to inductance. Also, the inductance needed to replace the missing 30-degrees of antenna depends on where it is sited, high, low, or in-between.

Siting affects performance as it determines current distribution along the antenna.

Where is the myth?

Best regards, Richard Harrison, KB5WZI

Can you describe that, please?

Parallel-wire feedline is used with success in 432MHz moonbounce which
are very sensitive to small losses. I don't have any information on
sharp bends, but T-joints and curved bends with say a foot radius cause
no noticeable problems.

West,

I would be thinking about a tail made from LMR-195. It is a low loss
cable, dimesionally compatible with RG58 connectors. One meter of it
has a loss of 0.25dB at 440MHz.

Nobody solders these things do they? Get a hold of crimp UHF and SMA
connectors suitable for RG58 and borrow a crimp tool to make them up.
Might be worth buying a couple of strain relief boots as well.

Alternatively, get a bit of old cellular cable, but it may have a
solid centre conductor... check it out.

Keep in mind that a run of 30m of RG8 has a loss close to 5dB at
440MHz, ie only 30% of the transmitter power reaches the feedpoint.

Cecil, thanks, I speed-read your extensive pointer.

The whole thing could be summarised in one short sentence -

"Coils are distributed transmission lines."

The same general equations apply to coils of all dimensions, for any number of turns, at all frequencies, in all applications. There's no need to unnecessarily complicate things by artificially dividing them into lumped and other varieties.

I had to skip over the bit about Smith Charts. As you are aware I don't know how to use one.

It seems Tesla, with HIS coils, knew what it was all about and he couldn't use a Smith Chart either.

> missing antenna to bring the vertical to resonance.

The myth is in thinking your 60-degree vertical is 90 degree resonant by virtue of an inductor "replaces about 30-degrees of missing antenna".

It does not do that.

Every real-world inductor behave to some extent as a transmission line, but unless the inductor is spatially large in terms of wavelength or unless the inductor has a termination impedance significantly higher than the shunting impedance caused by its own self-capacitance to the outside world the "transmission line" or radiation mode effects are negligible.

The ultimate in misunderstanding is when people think the loading inductor replaces a missing electrical degree length, rather than understanding a reasonably compact inductor primarily inserts a reactance that compensates for the capacitive reactance of the antenna system. Does it have some other behavior based on the fact it is less than perfect? Of course. No one is saying it doesn't have some limited effects!

If I have a 10 degree tall base loaded antenna it is a ten degree tall antenna. It is NOT 90 degree resonant antenna with "80 degrees of missing length" in the inductor, nor with that 80 degree long inductor behave like 80 degrees of antenna length would.

The very incorrect concept that an inductor and loaded antenna acts as a "80 degree coil and ten degree antenna" (substitute the numbers you want) is what kicked this whole thing off several years ago.

Hello, and the only fan antenna that I have any experience with is the
venerable 2-6 MHz twin fan transmitting antenna used on USN combat ships.
This antenna consists of two sets (port, starbaord) of three sloping wires
strung from a yardarm on the stack to the feedpoint on the deck. A VSWR
of 3 or less is typically achieved using a fixed passive LC network. By
design, most of the radiation actually comes from RF currents induced on
the stack by the fan wires. Sincerely,

But how much of that resistance term is the true radiation resistance of your short radiator, and how much is contributed by the coil and "ground plane" losses?

Resonating an electrically short radiator with a loading coil doesn't change the radiation resistance of the short vertical antenna (whip) itself -- and the r-f current able to flow in that whip is the source of practically all of the useful radiation that system can produce.

The loading coil makes it possible for a practical transmitter to deliver r-f power into that short antenna system, but doesn't change the fact that it is only the short radiator itself that provides the useful radiation. The system may have the net reactance of a resonant, 1/4-wave vertical, but it will still have the radiation resistance of the original, short radiator, and that radiation resistance is the primary determinant of system radiation efficiency when using these coil-loaded antennas.

I beg to differ.

If I have a 15 degree long physical antenna, center loaded at 10 degrees, with 5 degrees above the coil I do have a 15 degree physical antenna. That does not mean the antenna is NOT 90 degrees elctrically long! Resonance requires that the reactive components cancel both in amplitude and phase! Each reactive component introduces phase shift into the system. The antenna, without a loading coil, is composed of three terms: resistance [radiation and loss], self capacitance, and self inductance. In a shortened antenna the self capacitance dominates and the resultant phase shift is NOT zero. It is required to add inductance to achieve resonance [phase shift = 0]. If an antenna is electrically 15 degrees long and the self inducance does not reduce the reactive phase shift to zero PHASE SHIFT MUST BE ADDED TO THE ANTENNA for resonance. This phase shift is accomplished by the loading coil.

Now, when that antenna is fed with 1 ampere [Imax] at the base of the antenna and the feed current follows a cosine distribution to the base of the coil [I = Imax*cos(theta)][theta=10], you claim that the current exiting the coil is also Imax*cos(theta), or 98.5% of max value.

However, if we start with zero current at the tip, a valid initial condition, and let current increase by a sine function then I = Imax*sin(theta1][theta1 = 5 degrees] The result is simply 9% of max value. There seems to be a disconnect here. 98.5% = 9% ?????????

If you claim Imax @ 98.5% exits the coil and has a value of 96.6% [I2] at the tip then boundary conditions require total reflection. That requires a 180 degree phase reversal at the I2 amplitude to satisfy the boundary condition. Now the reflected current into the top of the coil is -I3 = 99.6% of -I2. The reflected current exiting the bottom of the coil is, by your reasoning -I3. The reflected current at the base is 96.6% of -I2, or 93% of Imax.

If I understand you correctly, then the measured value at the base of the 15 degree antenna is NOT 1 ampere but only 0.07 amperes.

Obviously, the coil is acting as something more than a simple L. It is adding and inductive phase shift. The vertical has capacitance to the local ground. The vertical also has a self inductance!! That self inducatance is insufficient to complete the 90 phase shift required for resonance. Therefore, I offer that the loading coil provides the required additional inductance for resonance.

Here's the reason why. In a standing wave antenna,
like a mobile antenna, the forward current and the reflected
current are 180 degrees out of phase at the tip of the antenna
and their phasor sum is zero. That is one of the laws of reflection
physics. Their phasors are rotating in opposite directions so they
must each rotate 90 degrees to be in phase and additive at the
feedpoint. That's simple geometry. Your above antenna loading coil
must contribute ~60 deg to the rotation of the forward and reflected
currents. There is nothing else existing in the antenna that can
accomplish that absolutely necessary function.

> Where is the myth?

The lumped circuit model is generating a logical blunder. That model
presupposes no phase shift through an inductance. Therefore, there
is no phase shift through an inductance. (Circular Logic) Fortunately,
the coil ignores our mis-applied man-made model and performs the phase
shift anyway. The actual myth is that there is no phase shift through
a 75m bugcatcher coil. That myth is rampant on ham radio web pages.

The lumped circuit model assumes the proof before a solution to
the problem is even attempted. It is a common mistake, known as
'petitio principii', in the solution of logic problems (also known
as 'begging the question').

Some folks have simply forgotten that the lumped circuit model
presupposes that no reflections exist. It cannot be used in a
standing wave antenna environment. Now that these folk have
been reminded of the technical facts, it will be interesting to
observe the results. Will the erroneous web page information be
corrected?

If the antenna is 15 degrees long, it is 15 degrees long. I'm not even
sure "90 degree resonant" is a viable phrase, or what it means.

Can I have a series tuned circuit that is "90 degree resonant"? Is the
radiation resistance the same as a 90 degree tall Marconi? Is the
current distribution the same?

If we go to twice the antenna's frequency is it 180 degree resonant?
Does it have a current maximum in the center and HV at each end?

This is as bad as the MFJ 20 foot tall vertical half-wave that covers
80 through 2 meters.

So what? No one disagrees with that. The series loading inductor
corrects power factor, or brings voltage back in pahse with current.
Nothing I've written or read disagrees with that.

That's because you have failed to realize the antenna has a triangular distrubution ABOVE the coil. I suggest you look at this link:

http://www.w8ji.com/Topload_Rad_res.bmp

> If I understand you correctly, then the measured value at the base of
> the 15 degree antenna is NOT 1 ampere but only 0.07 amperes.

Your misunderstanding appears to be rooted in thinking the antenna above the loading reactor has a sine distribution. It does not. It is basically triangular.

Unless distribution is correctly visualized, conclusions will be flawed.

It take a certain number of ampere-feet to radiate a given amount of power as EM radiation. When the spatial distance of the radiating element is reduced, the current has to increase. This is just another way of saying radiation resistance decreases, and current increases.

> Therefore, I offer that the loading coil provides the
> required additional inductance for resonance.

I'll agree with that. It corrects power factor. It forms a series resonant circuit with the capacitance presented by the antenna above the inductor.

The only thing you are missing is the current curves are nowhere like you assume in the whip above the coil. It's very well documented in hundreds of peer reviewed engineering texts that current takes on a triangular distribution in a very short radiator, and that the intetgrated current over the length of that radiator for a given radiated power always equals the same ampere-feet.

I suspect that the method is to go out and actually try to measure the antenna in question, and perhaps you are being a bit tongue in cheek here? It appears that while there are some general reasons for feedline radiation, the actual situation is so dependent upon the individual antenna setup as to defy any calculation.

Assumptions are part of any experiment, and I'm going to go under the assumption that there isn't a *significant* amount of vertical radiation coming from my antenna. Measurement of that could be grist for a later experiment....

I'm sure Richard doesn't believe that since that would be circular logic. It is a law of reflection physics that the forward current and reflected current are equal magnitude and 180 degrees out of phase at the tip of a standing wave antenna. It is a fact of physics that those two currents are back in phase at the feedpoint. Since their phasors are rotating in opposite directions, they both must undergo 90 degrees of rotation between the tip of the antenna and the feedpoint. So what you have to do is explain where 90 degrees of phasor rotation comes from if not partly from the coil.

If the coil doesn't rotate the phasors, then the whip must cause that rotation. So, Tom, explain to us how 12 degrees of whip causes 90 degrees of phasor rotation. That explanation should be very interesting. I, and probably Richard H., don't see any other way for the component currents to undergo a 90 degree phase shift. If you do, please enlighten us.

> It does not do that.

Not in every way, of course. A 30 degree coil certainly doesn't replace the radiating ability of 30 degrees of wire. Is that the point you are trying to make?

> Every real-world inductor behave to some extent as a transmission line,
> but unless the inductor is spatially large in terms of wavelength or
> unless the inductor has a termination impedance significantly higher

> negligible.

What you don't seem to realize is that a coil can be assumed to be completely lossless, including zero radiation, and essentially the same thing still happens. You obviously do not understand standing waves. Have you ever taken pencil in hand and sketched out the phasor sum of two nearly equal phasors rotating in opposite directions. If you ever did that, you wouldn't keep making that same silly mental blunder over and over.

Cling to that lumped inductance model for as long as you choose to delude yourself, Tom. It has been proven not to work in a standing wave environment. What is it about, "... one needs transmission line analysis (or Maxwell's equations) to model these electrically distributed structures. Lumped circuit theory fails because it's a theory whose presuppositions are inadequate. Every EE in the world was warned of this in their first sophomore circuits course", that you don't understand?

It is physically 10 degrees tall. The physical height is what determines the radiation pattern. It is electrically 90 degrees long. The electrical length is what determines the feedpoint impedance. Where does that 90 degrees of electrical length come from if not partially from the coil?

> The very incorrect concept that an inductor and loaded antenna acts as
> a "80 degree coil and ten degree antenna" (substitute the numbers you

Yes, and it is essentially correct. Your mistake in using a lumped circuit model in a standing wave environment has been going on for years. You are not alone in needing to correct your conceptual mistakes.

I infer the "myth" is that the 80-degree coil might radiate as if it had a physical length of 80-degrees. I had no idea that anyone would conclude that! Radiators in most cases depend upon their physical lengths, which may include the length of an exposed coil, for their radiation characteristics.

Glad everyone who responded gave sensible answers. I agree with W7EL too.

The intrinsic impedance of the radiator consists of its radiation resistance and its reactance. The proper loading coil can provide a net reactance at the feedpoint of the antenna system of ~ zero ohms, but that hasn't changed the radiation resistance of that short radiator.

So the coil-loaded, short radiator is not really "electrically" ~90 degrees long -- it just has the reactance of an antenna that is ~90 degrees long. The coil-loaded, short radiator itself still doesn't have the radiation resistance of linear, 1/4-wave antenna. That remains a function of the electrical length of the whip, itself, apart from the effects of the coil.

But Richard, that is what is meant by "electrical" length, that it has the
same phase shift as a ~90 degree antenna.

So the definition of electrical length you use excludes radiation resistance? That resistance is the only parameter giving any antenna the ability produce useful EM radiation in a practical antenna system. And that resistance is a function of the physical properties and configuration of the radiator with respect to the operating frequency.

Model a short vertical radiator in NEC, and check its impedance. If short enough, it could be something like 0.1 -j2500 ohms. Now add an inductive reactance to the system to reach resonance. NEC then will show 0.1 +/-0 ohms. Note that the radiation resistance term did not change.

That short system is resonant, but it certainly won't have the practical radiation efficiency of a full, 1/4-wave, linear radiator, even though they both have the same "electrical length" by your definition.

Maybe part of the myth is that the antenna must be resonant to work. Nothing could be further from the truth.

How about this thought experiment: Assume a too short for resonance monopole, that has its feedpoint impedance made non-reactive by the insertion of a "base loading coil." All kinds of arguments, including this one, arise about what the role of the coil is, what its current distribution is, how it affects efficiency and so forth.

To minimize these arguments, let's stop calling the inductor a "base loading coil" and call it part of an "L-network feedpoint matching network." Now the radiator isn't resonant and the resulting feedpoint reactance (and resistance) is matched separately with the external network.

Has the radiator current distribution changed? No. Does the inductor in the L-network "make up" some number of electrical degrees in the radiator? Not from my viewpoint.

Yes, of course a 60 degree coil obviously doesn't radiate like a 60 degree
piece of wire. The 60 degrees is merely the phase shift that a traveling
wave
current undergoes while traveling through the coil. I hope this is not
just a semantic problem. When someone says a coil replaces 60 degrees
of an antenna, he certainly doesn't mean for radiation purposes (unless
he is an absolute dummy). He simply means the coil causes a 60 degree
phase shift in the forward current, much like a 60 degree length of wire.
And that's all it means.

Of course not! Nobody is arguing otherwise. You are obviously confused
about what I, and others, are saying.

> That short system is resonant, but it certainly won't have the practical
> radiation efficiency of a full, 1/4-wave, linear radiator, even though

> both have the same "electrical length" by your definition.

Is this a straw man? Nobody has said anything remotely resembling any
argument otherwise. Electrical length doesn't have much to do with
radiation. The radiation resistance and therefore efficiency, is closely
associated with the physical length. Electrical length mainly has to do with
phasor rotation. If a traveling wave current phasor rotates 90 degrees while
flowing through a coil, the coil's electrical length is 90 degrees. That's a
pretty
simple concept. The coil can even be considered to be lossless and non-
radiating in some relatively efficient antenna systems without introducing
much of an error.

Nobody is disputing the current rise through a coil. In fact, I have
been pointing it out. The coil does distort the current away from
the nice cosine envelope of a 1/2WL thin wire dipole.

Your graphs show standing wave current which doesn't flow. (Its
phase angle doesn't rotate.) Therefore, the magnitude of the standing
wave current can be any value depending upon where it is located in
the system. Wes, please take a look at http://www.qsl.net/qrzgif35.gif
to find out why standing wave current can have any value and is thus
unimportant. EZNEC plots the current in much the same way that
you have. So are the EZNEC results wrong and yours right? The
fact is that a standing wave current plot is close to meaningless.
Why are we continuing to discuss standing wave current?

What we need to plot is the forward traveling wave current and
the reflected traveling wave current which are the two components
of your standing wave current graphs. Do you have any simulation
software that will plot the forward current and reflected current?
Nobody is going to understand what is really happening until we
get a plot of those two component waves or at least an estimated
graph of the underlying superposed currents.

In fact, how about your best estimate of a graph of forward and
reflected currents through the coil including phase shifts? Only
then are you likely to understand what we are talking about..

You can replace the antenna with a box containing a series resistor and capacitor, and except for the field there's no steady state way to tell it from an antenna. A physically small inductor such as a toroid will function exactly the same in both cases. (I limited it to being physically small, since a larger inductor will interact with the antenna's field.) So your explanation should work just as well when the inductor is in series with a simple RC as when it's in series with an antenna. I can easily write the equations describing the voltage and current at every part of the resulting RLC circuit, using circuit analysis techniques which have been around for over a century. You're saying either that they're wrong, or that you can tell by looking at the terminals of a black box whether it contains an antenna or a simple RC. Can you describe the method you'd use, restricting yourself to steady state measurements, how you'd tell the difference?

I think there are two problems:

1.) Cecil wants everyone to start using reflection wave models to analyze every antenna system in the world.

2.) Many people think a very short monopole antenna that is resonant is still 90 electrical degrees long, and that the inductor makes up the missing number of degrees, and the current taper across that inductor is some form of sine shaped curve.

Cecil is free to use whatever tools he likes. He doesn't work for me, and (thank God) I don't have to work for him! What he wants me or others to do is a moot point.

I am concerned about the commonly held but very incorrect view that current travels through an inductor turn-by-turn, and that a loading inductor somehow shifts the phase of and/or level of current to "make up for missing degrees".

My only concern is people not understanding how an inductor and short antenna actually behaves. That problem is worth attention.

This can be easily addressed by looking at a G5RV on 40m. On
40m, the feedpoint impedance at the dipole is about 500+j100 ohms.
The parallel twinlead matching section is about 110 degrees long.
The resonant impedance looking into the matching section is about
27+j0 ohms. So the G5RV matching section has indeed made up
about 110 degrees needed by the antenna *system*. The tuned
matching section has increased the electrical length of the antenna
system by 110 degrees so its a pretty good match for coax.. The
same goes for an antenna loading coil no matter where it is located.
If the short whip antenna system needs 60 degrees to be matched
(resonated) the coil provides 60 degrees of phase shift.
That's all we are saying when we say the coil replaces 60
of degrees of an antenna system.

And the basic argument is whether a lumped circuit analysis
can be used on a coil when reflections are present. The answer
is NO!

If an antenna system needs 60 degrees to be resonant, it can be
done in any number of ways. You can give it 60 degrees of
transmission line or you can give it 60 degrees of coil. But please
note that the 60 degrees of phase shift in the loading coil has
no effect on the phase of the standing wave current. The phase

of the standing wave current essentially doesn't change all up
and down a 1/2WL dipole. Why would you expect it to change
in a shortened monopole. The fact that it doesn't changing is
essentially meaningless. It doesn't change whether a coil is
present or not.

For what it's worth --

I've avoided this discussion for two primary reasons. One is that it saddens me to see this "controversial" topic being brought up yet again after having been discussed at great length a number of times before. There's no reason I can see for it other than Cecil's religious zeal and dogged determination.

The second reason is that I hate to be reminded how easily some people can be manipulated to wholly ignore well known physics and embrace alternate theories which are devoid of the ability to produce predictions or numerical results to demonstrate their validity. We live with it every day in our ordinary lives, seeing the astrology column in the newspaper (and learning that it's been a driving force behind top level government decisions), homeopathic remedies at the drug store, and so forth. It's hard to see it keep surfacing here also.

Fortunately, some very good, honest, and knowledgeable people have been doing a very good job of presenting the facts. These include Tom, W8JI; Ian, G3SEK; Wes Stewart, N7WS; and Gene Fuller, W4SZ. Anyone who is truly interested in understanding the topic (which is fundamentally very simple) would do well to read what those folks have written and are writing. Because they're dealing with facts and well known phenomena, they can back up what they say with numbers and the ability to explain the phenomena you see.

I'd like to add one note to particularly pay attention to Ian's postings on March 6 and 8 explaining the difference between an inductor and inductance. When I and others have spoken of a "physically small coil" we're talking about something resembling a pure inductance. As Ian and others have said, the first step in understanding this topic is to understand how the idealized component works. Only after that can you add the effects of coupling to external fields, which explain the current difference you typically do see between the ends of a real inductor loading an antenna. The red herring in this discussion is the attempt to attribute this effect to something fundamental about inductances, rather than the effect of external fields interacting with a real inductor of significant physical size. Part of this is understandable, because an inductor can be surprisingly small and still exhibit substantial current difference from one end to the other when in the field of a short antenna, because the field from the antenna is very intense. The field from the inductor is also quite large, making noticeable capacitive coupling nearly always present, which also provides a path for displacement current. So it's somewhat natural to assume that the current difference between ends is more fundamental than

it really is. But the argument has been taken well beyond reason by the zeal to explain every phenomenon by means of reflecting waves and packets of average power. It's not necessary at all, and all that does is to provide a confounding factor to obscure the simplicity of what's really happening. Since the basis for this approach is largely contrived and devoid of the ability to produce quantitative results, it's easy to make pronouncements which can't be verified.

It's pretty obvious that objects in motion come to rest naturally without any external force. You reach this conclusion by failing to separate the external force of friction from the inherent inertia of the object. The problem here is exactly the same -- people are failing to separate the phenomenon of external coupling from the inherent properties of inductance, and concluding that observed current differences between the ends of loading inductors are caused by some inherent property of inductance.

I can imagine people arguing about the basic property of objects to spontaneously come to rest long after Newton proved it otherwise. Actually, I wouldn't even be surprised if there's some Newtonian Cecil who's still arguing about it.

Ian, GM3SEK wrote:
"Can you describe that please?"

Gladly.

For low loss at 100 KW, you use large cable and wide spacings at 600 ohms. It may have been more economical to use more conductors but for simplicity we stuck with a 2-wire balanced feed system. We had at that particular time and location the largest congregation of high-powered shortwave transmitters and directional antennas in the world. We installed a crossbar switching system so that almost any transmitter could access any antenna. We were on the air with most transmitters operating nearly 24 hours a day, but switching antennas several times a day according to our announced program schedule to accommodate anticipated propagations to the target areas served.

Ed Laport as Chief Engineer of RCA International had as much experience as anyone with commercial shortwave radio, so we relied upon him for information and weren`t disappointed.

On page 396 of "Radio Antenna Engineering", Ed illustrates a corner made using two transmission lines. He shows a single pole with two crossarms, one above the other and making the horizontal angle required for the intersection. He terminates the lines one on each crossarm. Jumpers are used to interconnect the two lines.

Our line cables were akin to welding cable. We joined them with sleeves and fittings attached with a hydraulic press (Nicropress). With wide spacing the lines are tolerant of bumps and don`t tend to flashover.

Ed gives a graph of the value of the ratio of line spacing to cable radius versus Zo. For 600 ohms the ratio is about 150.

Best regards, Richard Harrison, KB5WZI

You're missing the point, Roy. It indeed does function the
same way in both cases but if there are reflections present,
your lumped circuit analysis rules are known to fail.Your
analysis of both cases may be equally wrong in both
cases.

What is the traveling wave current delay through the coil in
degrees? That's easy to measure. That current delay is the
degrees that the coil supplies to the antenna. You can ignore
any measurements involving standing wave current as being
essentially meaningless. What is important is the traveling-
wave current delay through the coil. Please measure it and
report what it is for your 'physically small toroid'.

Your lumped circuit analysis pre-assumes a zero delay
through the coil. That delay is certainly not zero in the real
world.

No, I simply want you and others to stop using a known invalid
model for every standing wave antenna system in the world.
This is a quote from the first web page below: The capital
letters are where the author used bold italics for emphasis.

"... - no wave interferrence and no standing waves can be
present on lumped elements. The problem has been that many
experimenters working with self-resonant helices have
PURSUED THE CONCEPT OF COIL SELF-
CAPACITANCE WITHOUT REALLY UNDERSTANDING
WHERE THE NOTION COMES FROM OR WHY IT WAS
EVER INVOKED BY ENGINEERS. For that, they will have
to go read R.W.P. King's wonderful old book, "Electromagnetic
Engineering, McGraw-Hill, 1945. ... On page 465, the Harvard
Professor points out that, for coils whose *wire length* exceeds
1/6 wavelength, ...'an adequate representation of the reactance
of a coil with a nonuniformly distributed currentr is NOT
POSSIBLE in terms of a coil with a uniform current [a lumped
element inductance] ...' Period. Resonant FIELDS present
surprises to engineers with limited training."

Certainly sounds like he is talking about you, Tom. "Electronic
Engineering" was written before you were born. Why are you
ignorant of the technical facts presented in it?

http://www.ttr.com/corum/index.htm

http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

The .pdf paper is a pier-reviewed publication by the IEEE. Here's
what it says about the model you have chosen to use.

"Of course, the uniform current assumption has no validity for coils
operating anywhere near self-resonance!"

"The failure of any limped element circuit model to describe the
real world lies at its core inherent *presupposition*: the speed of
light is presumed to be infinite in the wave equation. ... Consequently,
lumped element circuit theory does not (and cannot) accurately
embody a world of second order partial differential equations in
space and time."

"The concept of coil "self-capacitance" is an attempt to circumvent
transmission line effects on small coils when the current distribution
begins to depart from its DC behavior."

"There are a great number of formulae for coil self-capacitance.
None are of particular value for quarter-wave helical resonators
anywhere near the 90 degree point."

"The delusion is that the short coil is then made to operate in the
lumped element regime ...".

That you refuse to give up on an invalid method in the face of
overwhelming evidence is amazing.

> What he wants me or others to do is a moot point.

Afraid of what you will find? The first web page above says:
"Lumped circuit theory isn't absolute truth, it's only an analytical
theory - and in these resonators we have the case where this
sophmore theory fails experimentally." Do the experiment, Tom,
and discover exactly how sophmorish you are being.

> I am concerned about the commonly held but very incorrect view that
> current travels through an inductor turn-by-turn, and that a loading
> inductor somehow shifts the phase of and/or level of current to "make
> up for missing degrees".

Tom, that's what any matching network does. Loading coils are no
exception.

> My only concern is people not understanding how an inductor and short
> antenna actually behaves.

I am concerned about you not understanding, Tom. Don't
you believe the information posted on those web pages above. Don't
you think a peer-reviewed IEEE publication that disagrees with you
is worth a second thought from you. Don't you think ignoring the
knowledge published by experts in the field is a little naive?

The reason is that you are wrong and I have provided expert testimony
that you are wrong. I'm trying to stop you from speading false information
so don't fault me for that. The fact that you refuse to have a technical
discussion with me in spite of the numerous expert postings that
prove you are using an invalid model, speaks volumes. The results
of the spreading of lumped-circuit analysis myths is that you are
hoodwinking the uninitiated.

> Fortunately, some very good, honest, and knowledgeable people have been

This is an argumentum ad verecundiam, a well known logical
diversion and not a technical argument. I have quoted just as many
experts and you have ignored them. In particular, R.W.P. King is
quoted from "Electromagnetic Engineering": ... for coils whose
wire length exceeds 1/6 wavelength, an adequate representation
of the reactance of a coil is *NOT POSSIBLE* in terms of a coil
with a uniform current [a lumped-element inductance]..."

Roy, my 75m bugcatcher coil, made from 44 feet of wire, is more
than 1/6 wavelength of wire. R.W.P. King says your lumped-circuit
analysis is *NOT POSSIBLE*. He used bold print and underlined the
words, *NOT POSSIBLE*. Ignoring the quotations from the true
experts is just going to leave you ignorantly spreading old wives'
tales. Is that really how you want to be remembered here?

Why are all of you alleged "experts" unwilling to discuss technical quotes
like R.W.P. King's above? Are you afraid that readers will discover
your common mistake which Dr. Corum calls "sophomoric"?

As Dr. Corum says: "There are no standing waves on a lumped
element circuit component. (In fact, lumped-element circuit theory
inherently employs the cosmological presupposition that the speed
of light is infinite, as every EE sophomore should know."

Why do you choose to absolutely ignore that technical knowledge?

Summary of design of a short loaded vertical antenna.

There is a 90-degree phase shift between the feedpoint and the tip of the antenna.

With a short antenna most of the 90 degree phase shift is due to the loading coil which is, in effect, a transmission line.

The transmission line has Zo, velocity, phase-shift and some attenuation due to radiation resistance plus wire loss resistance.

Radiation resistance and phase-shift are directly proportion to coil length, as are L and C and wire resistance.

Q = Omega*Total Inductance / Total R as is usual. Bandwidth = Resonant Freq / Q.

Radiating efficiency takes into account wire resistance below the coil, coil resistance, resistance of the wire above the coil, plus ground loss resistance, plus the sum of the three radiation resistances. All resistances are referred to the antenna feedpoint.

With short coils, radiation resistance of the coil is usually much less than that due to the length of the wires above and below it. With a helical antenna, wire loss resistance is always greater than its radiation resistance.

At low HF, with a good set of ground radials, the loss resistance of coil wire usually predominates. At high HF, the ground loss usually predominates but the radiation resistance becomes important.

The whole business is calculable. There are few rules of thumb. The only thing which is missing is the radiation pattern. If you don't already know what the radiation pattern is in the vertical plane then Eznec will attend to that. Actually, in the vertical plane, radiation is approximately proportional to the cosine of the elevation angle. The horizontal groundwave is stongest.

Some of the parameters need not be explicitly calculated.

EXAMPLE:

Starting data:
Height of antenna below coil = 2 metres = 79 inches.
Diameter of antenna below coil = 25mm = 1 inch.
Length of antenna above coil = 1 metre = 39 inches.
Diameter of antenna above coil = 10mm = 0.4 inches.
Length of coil = 152mm = 6 inches.

Diameter of coil = 76mm = 3 inches.
Overall antenna height = 3.152 metres = 124 inches = 10.3 feet.
Ground electrode loss resistance = 5 ohms.
Frequency = 3.8 MHz.

Calculated data:
Number of turns on coil = 53
Wire gauge = 13 or 14 awg.
Radiating efficiency = 10 percent.
Loss relative to full-size 1/4-wave vertical = 9.4 dB.
Self-resonant frequency of the coil = 8.2 MHz.
For maximum efficiency the coil is located at 50% of the overall
antenna height.
But there's not much extra loss by using base loading.

For other calculated data use program LOADCOIL which is about 6 years
old and I think I have lost the source code.

I will accept what you find as long as long as the method to
obtain the results is valid.. Roy's earlier measurements are
virtually meaningless since he was measuring standing wave
current which doesn't even flow (phase is constant and
fixed around zero degrees). You guys always seem to
make measurements that support your preconceived
notions and avoid measurements that don't

But you have already started what I am asking, Tom. You
measured a voltage phase shift of 60 degrees through a
100uH coil at 1 MHz. The current is known to lag the voltage
through a coil so the current phase delay is more than 60
degrees. I wouldn't be surprised to see it at 120+ degree
lag in the current. So your own experiment proves you are
wrong. How do you get away with such behavior without
anyone noticing?.

(Hint: there are a handful of knowledgeable lurkers who
have noticed.)

When you measured S12, was the load side of the coil
looking into 50 ohms?

In the web pages I previously posted, R.W.P. King, in
"Electromagnetic Engineering", asserts that you cannot
use a lumped circuit analysis on a coil containing 1/6

wavelength of wire. Your 100uH coil above exhibits
60 degrees of phase shift even for the voltage and that's
1/6 wavelength for voltage - even more for current. The
lumped-circuit model assumes that the voltage is traveling
at an infinite speed, faster than light. Since you believe so
strongly in the lumped-circuit model, wonder why your
measurement didn't reflect that fact? :-)

Richard, lest you get nit-picked to death again, let's be clear
that you are talking about a standing-wave r-f environment.

If a coil is installed in a traveling-wave r-f environment, with
no standing waves, the magnitude of the current through the
coil will be the same at both ends, minus losses.

It's the phasor sum of the forward and reflected current phasors
that causes such a large variation in coil current in a standing-
wave r-f environment illustrated by the graphic at:

http://www.qsl.net/w5dxp/qrzgif35.gif

Wonder why none of those resident gurus have bothered to
explain the current distribution in that coil? Have you noticed
my questions about the technical references that I have
provided just keeps piling up with no responses?

Standing wave net current doesn't flow back and forth
along the wire. That's why they call it a *standing* wave.
Why don't you know that already? At any point on the
wire, the H-fields and E-fields are exchanging energy at
the frequency of operation. That's certainly enough reason
for an inductive pickup to respond.

Why is that a surprise to you or Roy? Because you two
mistakenly thought net standing wave current flows and
ignorantly measured it? All you measured was the
orthogonal exchange of energy between the two fields.
Nothing was moving except the underlying forward and
reflected currents. Isn't this stuff taught anymore?

What have you guys done - gotten together and elected
yourselves into a club of omniscient gurus? Please take
a look at the laws of reflection physics. It appears that
you are ignorant of most of them.

The only thing worth noticing is you are misrepresenting facts.

I measured current with a small current transformer, and current at each end of the inductance was, as close as my two-channel vector voltmeter will resolve, equal in phase and equal in level. I read about .695 volts from the current transformer secondary on each end of the coil from the current transformer secondary with zero phase shift.

The only thing shifted in phase was voltage when referenced to the output terminal. The load resistor voltage shifted phase from generator voltage. Of course generator current lagged generator voltage by the same amount.

Well, I guess you are surprised. Now let's hear your personal attack or excuse.

Indeed. Or alter his interpretation to fit the data. Anyone interested in seeing the results of careful measurements should see the "Current in antenna loading coils controversy (long)" in November 2003, where I made and reported just such measurements. Pay careful attention to Cecil's various predictions of what the results would be using his method of explanation.

Cecil,

A few random comments:

* I have done a number of "peer reviews" for IEEE and AIP publications as well as other publications. I have seen comments from the other reviewers. In general peer review is better than nothing, but in many cases it doesn't mean diddly.

* The Tesla coil crowd seems to contain an unusually large fringe. I know nothing of the authors of your latest bible, but in any case I was not particularly impressed with their credentials or their paper. I love the part, "Lumped circuit theory isn't absolute truth, it's only an analytical theory about lumped models". As if their work is somehow absolute truth. (Back to the previous bullet: I have never seen any serious peer-reviewed paper that would contain such a statement.)

* No one is his right mind would think that a Tesla coil with a gazillion closely spaced turns is equivalent to a bugcatcher coil. No one should think that an axial mode helical antenna is equivalent to an ordinary loading coil either.

* You are waaaay too hung up on the subject of standing waves vs. traveling waves. You may have noticed that the standard treatments of antennas in texts and other references barely mention the terms. They merely discuss the actual current in the antenna. The fundamentally important entity in radiation is accelerated charge, just as Tom noted. At any point in an antenna, such as the loaded monopole discussed here, there is simply a current, not a traveling wave or a standing wave. If you could examine the antenna microscopically at a single point you would find electrons sloshing back and forth. You could not tell if the current was represented by a standing wave or a traveling wave. The standing wave description relates to the overall amplitude characteristic of the current when you look at the entire antenna. This amplitude characteristic is certainly important in calculation of details of the radiation field, but it does not change the fundamental property of radiation or the physical processes ongoing in the antenna. It is just plain silly to argue that a standing wave is totally inert and does not flow back and forth.

* Distributed or network models are mathematically convenient for treating complex problems. However, they add precisely zero new information to the underlying physical reality described by Maxwell's equations. They offer no new physics beyond lumped models. They can be misapplied just the same as lumped models can be misapplied. It is generally best to drive a nail with a hammer, but a monkey wrench will

also do the job. It is best to choose the most efficient tool, but that
does not mean others won't work.

>Why are we continuing to discuss standing wave current?

Well, I certainly hope that EZNEC plots the current the same. If you
would have read all that I wrote in the reference, you would have see:

"The models were "built" using MultiNEC invoking EZNEC 3.0 (now 4.0)
or double-precision NEC-2 as the calculating engines. The following
graphics were all generated with MultiNEC."

Among the other nice things that MultiNEC does is interface to many
other analysis programs, EZNEC being my preferred one, and gives some
other ways to present -the same data- in other forms. The data in the
figures are EZNEC-calculated-data.

Clearly, you were too busy trying to frame an argument to actually
read what I wrote.

>

>then are you likely to understand what we are talking about..

If "we" includes you and me, I will never understand what "we" are
talking about, although I am pretty sure what "I'm" talking about.

Now, I've got to get back to something important; building a playhouse
for my granddaughter.

Regardless of the T-line length, it will be a 2:1 mismatch. If the line
is 1/4 wave long, then the Tx will "see" 100 ohms.

Leaving one end of the "T" open will provide no significant effects up
through UHF, but it does represend a very short section of open line in
parallel, which, as Dan reports, will show as a small capacitance.

This, by the way is a good way to check an SWR meter for accuracy,
providing, of course, the loads you use are pretty good as well. You can
easily do 2:1 and 4:1 (with two "T"s and four loads) if you have them.

P.s. If you needed to, and it was a good 50 ohms, you could use an antenna
for one of the loads.

Here are your words cut and pasted from qrz.com.

> "By the way, I swept S12 phase with my network analyzer on a
> 100uH inductor a few hours ago while working on a phasing
> system. The phase shift through that series inductor was about
> -60 or -70 degrees on 1 MHz, ...

S12 is a voltage parameter. So did the coil show a "-60 or
-70 degrees" voltage phase shift or not? Where does it say
anything about "current with a small current transformer"
in your posting? Last time I looked, a 100uH inductor was
not a small current transformer. I assumed a current
phase shift at first and you jumped on me about that. Now
you say it was a current phase shift after all. If you want
to be quoted correctly, you need to stop fibbing.

Here's what I think happened in context. You were trying to
prove Kraus wrong with his assertion that a 180 degree
phasing coil can be thought of as 1/2WL of wire wound
into a coil. You failed to realize that your posting was
supporting my other point about phase shifts through coils.
So you accidentally posted results that supported my side
of the argument. Your lumped-circuit model predicts zero
phase shift. My distributed network model predicts considerable
phase shift. Your experiment yielded considerable phase shift
and now you seek to deny it. However, it is there in all
its glory on qrz.com for all to see. So feel free to deny it.

> The only thing worth noticing is you are misrepresenting facts.

I never misrepresent facts as I understand them to exist. The fact that you absolutely refuse to engage me in a technical discussion speaks volumes. If I were wrong, you would simply engage me and prove me wrong with a technical argument as you have so many others. But If I am right, I fully understand your reluctance to engage me in a technical discussion.

You can start the technical discussion by explaining the EZNEC results on my web page:

http://www.qsl.net/qrzgif35.gif

Why are all you gurus so reluctant to discuss that topic? I have asked you guys to respond to that graphic at least half a dozen times and got only one weak reply. Why the silence?

I have this book. The condition for the quoted result isn't simply that the length of wire in the coil be adequately long, but also that the coil be wound loosely enough so that the coupling between turns is poor enough to allow a particular nonuniform current distribution. It applies to a "loosely wound helix." The quote is within a section titled "'Lumped' Constants in Near-zone circuits", which contains a detailed analysis of just what conditions can cause an inductor to have unequal input and output currents, but primarily how the currents can be unequal even in the absence of an external field. In particular, the author describes an inductor in which the coupling between turns isn't sufficient to force equal currents at the coil ends. Qualitatively, this should be pretty obvious: If we begin with a long wire (in terms of wavelength), the current will vary along its length. As we wind it into a loose coil, mutual coupling between turns will create inductance and make the current more uniform, but with a distribution still resembling that of the straight wire. It's this situation that the quotation applies to -- an inductor so loosely wound that its current distribution resembles a straight wire more than an inductance. He does go on to say that if the winding is tighter but still not ideal, the resulting non-uniform current, which has a different distribution (greater at the

center than at the ends), can be modeled by means of a lumped self capacitance. Only if we have perfect coupling between turns (as a toroid very nearly represents) will we truly have equal currents at input and output, for the reasons Tom recently explained. This is the idealized inductance which some of the contributers to this discussion are having trouble understanding.

The mathematical treatment in King is quite complex. But nowhere does he mention any traveling, reflected, or standing current, power, or energy waves, or that an inductance behaves any differently in an antenna than in a lumped circuit. It simply isn't necessary or relevant to explaining the operation of either an ideal or non-ideal inductor. Nor does he dispute the fact that the currents into and out of an ideal inductance are equal. And of course there's no mention of the mysterious "resonant fields" which probably do surprise engineers, as does the metaphysics being promoted here.

Translation: If they don't agree with Gene Fuller, they don't mean
diddly. :-)

> * No one is his right mind would think that a Tesla coil with a
> gazillion closely spaced turns is equivalent to a bugcatcher coil.

On the contrary, Gene, my 75m bugcatcher meets the minimum
definition of a Tesla coil on 9-10 MHz where it is 1/4WL
self-resonant, i.e 90 degrees. It is a good 78 degrees on
75m which is not all that far from its self-resonant point.

> * You are waaaay too hung up on the subject of standing waves vs.
> traveling waves.

So uttered by the priest of the high-and-mighty lumped-constant
religious sect. :-) The lumped-circuit model is known to fail in
a standing-wave environment. Anyone using it in a standing-wave
environment is doomed to failure. Those are known facts. What
is it about those statements that you don't understand?

> At any point in an antenna, such as the loaded monopole discussed here,
> there is simply a current, not a traveling wave or a standing wave.

Gene, if you want to assert that the current on a standing wave
antenna is not a standing wave, be my guest. The standing wave
on a 1/2WL dipole is why it radiates broadside. If it were a
traveling wave, it would be an end-fire. Standing wave current
is NOT traveling wave current and vice versa. I'm not even sure
that "standing-wave current" even meets the definition of
"current". If it's not flowing, is it really current? It appears
to me to be more of a wet dream than anything real.

> If
> you could examine the antenna microscopically at a single point you
> would find electrons sloshing back and forth.

But we are not interested in Brownian motion, are we? We are
only interested in the net charge flow and that is zero on a
standing wave antenna with equal coherent currents flowing
in opposite directions.

> You could not tell if the
> current was represented by a standing wave or a traveling wave.

Say what? If voltage/current maximums/minimums exist, then a
standing wave exists. Admittedly, if you were an individual
electron, you would have trouble discerning the difference.
But Gene, if you really are an individual electron, please
explain to the group how you manage to depress the keyboard
keys?

> It is just plain silly to argue that a standing wave is totally inert
> and does not flow back and forth.

Where did that word, "inert", come from? Not from me. Do I
smell a straw man arising?

When you have equal magnitude coherent waves flowing in opposite
directions in a wire, do you really want to assert that there is
a net charge flow or a net current flow along the wire? If so, be
my guest and please prove it.

> * Distributed or network models are mathematically convenient for
> treating complex problems. However, they add precisely zero new
> information to the underlying physical reality described by Maxwell's
> equations.

Exactly correct!

> They offer no new physics beyond lumped models.

Exactly incorrect. Lumped-circuit models are a subset of distributed-
network models. Distributed-network models are a subset of Maxwell's
equations. Lumped-circuit models are known to fail in the presence
of standing waves. That is what the whole argument here is about.
Some people have adopted the lumped-circuit model as their religion
and they will attempt to put anyone who disagrees with them under
house arrest, as happened to Galileo, e.g. W7EL has 'ploinked' me
and uses his guru status to take unfair potshots at me from time
to time.

What we have on this newsgroup is a gang of junk yard dog gurus who
don't care if they are right or wrong. They just attack anyone who
disagrees with their postings whether right or wrong. (It's not ad
hominem when it's the truth and any knowledgeable person following
this discussion recognizes that as the truth.)

I would like to request that everyone stop the ad hominem attacks,
(me included), and engage in a civil gentlemanly technical
discussion. If I am so wrong, I should be easy prey for 4+
distinguished gurus. OTOH, if I am right, I understand the reluctance
to engage me on a technical level and fully understand the ad hominem
attacks to be a face-saving necessity. So which will it be? The
response to my technical quotes and assertions has, so far, been
underwhelming. Shouldn't half a dozen omniscient gurus be able to

dispatch a mere mortal grasshopper?

This is a public forum. Why do you not respond to my posting on
a technical level instead of resorting to an ad hominem attack?
I have tons of technical references to support my position.

> Clearly, you were too busy trying to frame an argument to actually
> read what I wrote.

I only respond to portions I disagree with, Wes. Why can't
you and I have a simple, point by point, technical discussion?

> "We" need to plot no such thing. You may have such a need; I do not.

You, nor your cohorts, are likely to understand what's really
happening until you take a look at the individual underlying
currents that superpose to form the standing wave current which
doesn't flow at all since its phase angle is fixed at zero degrees.

Isn't a bunch of IEEE PhD's saying that "the lumped-circuit model
fails in a standing-wave environment", enough evidence for you to
consider that they know what they are talking about?

Please define the point at which a "loosely wound helix" with
a varying current turns into this lumped-circuit device that
forces equal currents through the coil. Is a 75m bugcatcher
coil a "loosely wound helix" or a "lumped-circuit"?
(My 75m bugcatcher coil is about 1/6 wavelength of wire.)

> Only if we have perfect coupling between turns (as a toroid
> very nearly represents) will we truly have equal currents at input and
> output, for the reasons Tom recently explained. This is the idealized

> trouble understanding.

Unfortunately, an idealized inductance is like a lossless transmission
line - it exists only in the human mind. What I would like to know is
what is the real-world phase shift through your toroidal inductor when
there is only a traveling wave (no standing wave). We can then use
the laws of reflection physics to determine what effect that phase
shift has on the amplitude of the standing wave current which is the
phasor sum of the forward current and reflected current. I'm actually
going to make those measurements as soon as I get off my old lazy ass.

Seems to me that although a toroidal current pickup may not have the
same magnitude characteristics because of variations in the permeability,
the phase would suffer no such effects. Am I correct on that point?
I'm somewhat handicapped in having no current probes for my 100 MHz
Leader and acquiring them would put a big dent in my Social Security
check. :-)

What I am toying with is a 6m rhombic. I could run it as a terminated
traveling-wave antenna or unterminate it and have a standing-wave
antenna. I could move all kinds of coil(s) up and down the the elements
to place them at nodes or loops or in-between and take measurements.
What do you think?

> S12 is a voltage parameter. So did the coil show a "-60 or
> -70 degrees" voltage phase shift or not?

It did. Just as I posted here it did.

>Where does it say
> anything about "current with a small current transformer"
> in your posting?

It didn't. As I kept telling you in that thread, I didn't want to talk to you until you were able to make a post without resorting to personal attacks. I also told you I was busy with work, and didn't have time to deal with the same old circular arguments with you.

> Last time I looked, a 100uH inductor was
> not a small current transformer. I assumed a current
> phase shift at first and you jumped on me about that. Now
> you say it was a current phase shift after all. If you want
> to be quoted correctly, you need to stop fibbing.

Please stop trying to blame your mistakes on me! It's not my fault you assumed more than you read! I've been telling you all along current at each end of ANY small inductor has the same phase. I've been telling you all along I didn't want to talk to you until you learn to behave.

Don't accuse me of lying because you made up a theory and it is dead wrong! It isn't MY fault you painted yourself in a corner by adjusting your theories to suit what you thought was said, when it wasn't even said.

> Here's what I think happened in context. You were trying to
> prove Kraus wrong with his assertion that a 180 degree
> phasing coil can be thought of as 1/2WL of wire wound
> into a coil. You failed to realize that your posting was
> supporting my other point about phase shifts through coils.

"Here's what I think" is correct Cecil. In your mind Cecil, it's always all about the other guy failing, being wrong and knowing better, or being dishonest.

> So you accidentally posted results that supported my side
> of the argument. Your lumped-circuit model predicts zero
> phase shift. My distributed network model predicts considerable
> phase shift. Your experiment yielded considerable phase shift
> and now you seek to deny it. However, it is there in all
> its glory on qrz.com for all to see. So feel free to deny it.

Anyone can read anything. I'd wager you anything you like multiple people on this list can make a small current transformer, measure current at each terminal of a compact inductor, and find the phase of current essentially the same at each end.

It isn't about me Cecil. It isn't about Kraus. It isn't about QRZ. It isn't about Roy or anyone else. It's all about how a two terminal inductor acts! That can be proven over and over again, and it will always come out the same. Neither you nor I can change how things work.

> I never misrepresent facts as I understand them to exist. The
> fact that you absolutely refuse to engage me in a technical
> discussion speaks volumes.

It does indeed. If you stayed away from personal attacks I would converse with you. I've told you that over and over again. People who say things on Internet they wouldn't say face to face wear on my nerves. I find it very difficult to remain civil when reading constant personal attacks.

>If I were wrong, you would simply
> engage me and prove me wrong with a technical argument as you
> have so many others. But If I am right, I fully understand your
> reluctance to engage me in a technical discussion.
> You can start the technical discussion by explaining the
> EZNEC results on my web page:

1.) We really can't have a good conversation until you stop the constant personal attacks, and until we agree on a few basics.

2.) You claim Roy measured current that doesn't flow. That area needs addressed.

3.) You also claim significant current phase shift exists between the terminals of a compact inductor operated well below self-resonance.

It's very simple to measure current and voltage and the phase relationships in a two terminal device and prove you are wrong.

Trying to divert the issue to me not following your commands and orders just won't go far.

The current flowing into one end and out of the other end of a small lumped inductor operated far below self-resonance is essentially equal in both phase and amplitude. You say it isn't, I say it is, and I can prove it beyond any doubt to any open minded person.

I say I can easily build a loading coil that acts the same way. I can replace 40 or 60 degrees of electrical height with an inductor that has virtually no phase shift in current between the two terminals, and virtually the same current level. I can prove that also.

I'm just not sure I can prove anything to someone who thinks a current transformer measures current that doesn't flow!

Your diversions are comical and obvious, Tom. Thanks for
the laugh.

> If you stayed away from personal attacks I would converse with you.

Pot, Kettle. Kettle, Pot. Tom, your personal attacks are legend
throughout the internet and world wide web. I know hams who
are too terrified to respond to you even when you are wrong.

> 1.) We really can't have a good conversation until you stop the
> constant personal attacks, and until we agree on a few basics.

Hard to accomplish since you define being proven technically wrong
as a personal attack.

> 2.) You claim Roy measured current that doesn't flow. That area needs
> addressed.

Please explain how a net current with a fixed constant
non-rotating phase can possibly flow. Please explain
how a wire with 1 amp flowing in one direction and 1 amp
flowing in the other direction supports a net charge flow.

> 3.) You also claim significant current phase shift exists between the
> terminals of a compact inductor operated well below self-resonance.

Please define "compact" in terms of the number of degrees
of phase shift measured using a traveling wave.

> It's very simple to measure current and voltage and the phase
> relationships in a two terminal device and prove you are wrong.

I've got many technical references that disagree. If you can do
that, why haven't you done that?

> The current flowing into one end and out of the other end of a small
> lumped inductor operated far below self-resonance is essentially equal
> in both phase and amplitude.

Please define "small" as the number of degrees of phase shift
measured using a traveling wave.

> You say it isn't, I say it is, and I can
> prove it beyond any doubt to any open minded person.

Here, you are just out and out lying since I never said that.
Want to bet $1000 that you can prove I ever said that? I didn't
think so. What is with this compulsion you have to lie about
what I have said? Can't you win a technical argument without
lying?

> I say I can easily build a loading coil that acts the same way. I can
> replace 40 or 60 degrees of electrical height with an inductor that has
> virtually no phase shift in current between the two terminals, and
> virtually the same current level. I can prove that also.

I seriously doubt that. Please measure the phase shift using a
traveling wave through any coil that accomplishes that function.
I suspect you are being fooled by the current loop located inside
the coil and the fact that you have been ignorantly been measuring
the net standing wave current which is essentially irrelevant.

> I'm just not sure I can prove anything to someone who thinks a current
> transformer measures current that doesn't flow!

I explained it to you, Tom, in another posting. If you don't
understand it, you need technical help. At a fixed point on a wire
(where no net current or net charge is flowing) that is experiencing
a constant exchange of H-field energy with E-field energy every
cycle, a toroidal pickup coil will certainly report the results of
that orthogonal energy exchange between the fields even though there
is no lateral flow of net current or net charge. That's why a
standing-wave dipole radiates broadside and a traveling-wave
dipole is an end-fire. What school did you say you attended?

Wow, thanks for the offer. That would certainly be more
accurate than eyeballing an o'scope. Do you think the
use of such would prove me right or wrong? Does the
VV compare two signals and report the phase difference?
Are the probes differential or coaxial? I've never used
a VV.

Source record: 63427

I know this has been addressed on the group before but I remain confused.

I will string a dipole in the trees. The coax shield will be earth grounded, as well as the balun and lightening arrestor.

Now, in the 2nd floor shack, I've read that running a ground line from equipment 15 feet or more (in this case) to an earth ground will bring RF into the shack and be a potent source for TVI, etc.

My choice, then, is to use the ground on the mains.

Given that the shield is earth grounded on the antenna and the equipment is grounded to the mains, isn't this a good scenario for ground loop?

Seems like a catch-22.

My own gut says safety first, lower risk of RF issues after-the-fact by
? what ?

I remember suggestions of coiling the ground wire in an RF choke, multiple ground lines of various lenghts to mess with harmonics. Ferrite beads? Chicken blood and a black cat?

I had to do some research to find out that a UG 21 is just and N
connector. I'm not sure why you are surprised people are using them.
The are about the same size connector as a UHF which is very common in
ham radio, and the N is a much better connector. I put N connectors on
all of my antennas, especially if they are going to be out side. But
yes I would be interested in one of those Sage 1021H adapters. I have a
few extra 1N21 diodes if you want to make a trade or I can just send
money. Do you take paypal? Let me know what you want for them.

Hi Cecil

I dont know how to use a VV either. I got a couple of them from Pacific Missile Range surplus. One has a probe sheared off. I figured I could build a "pair of probes" to make that one work for myself. You are welcome to have the other. That one looks complete.
It sure would be worth the effort to ship it to you if you'd like to have it.
I cant guarentee that the 8405A works but I do know they are repairable.
If you are willing to check it out, its yours.
I downloaded a manual for the unit. E-mail me your address. Maybe you can tell me something about the unit after you figure it out.

I have such a high respect for Roy and Wes that it is not possible for me to think they'd both be wrong while in agreement. And, I like to read your discussions on this group so much that I'd offer anything I can to assist your 'getting some measurements made'. I am absolutely sure all you guys will agree on this stuff after you make some measurements. You are all too bright to have such severe differences in understanding on this subject.

The VVM probes are comprised of a quad diode sampling bridge followed by an FET amplifier. They are nominally coaxial, although without the BNC adapters, they have an exposed pin (very delicate) and at lower frequencies they can be used much as a high impedance scope probe is used.

The instrument uses a phase-locked oscillator to drive the samplers with the "A" probe being the reference. One meter can be switched to display the amplitude of either channel and the second meter reads the phase difference between them.

I don't hate you. While I shook your hand at Flagstaff once, I don't know you well enough personally to get all worked about you one way or another.

This is Usenet, not the real world. No sense taking it too seriously.

I have no "cohorts" here. This isn't the "Let's get Cecil" gang.

>
>Isn't a bunch of IEEE PhD's saying that "the lumped-circuit model
>fails in a standing-wave environment", enough evidence for you to
>consider that they know what they are talking about?

I've worked with lots of PhD's. Hell I even had one working for me
and his was in Nuclear Physics from Trinity College at Oxford. He was
a lovely old guy, the quintessential Einstein type, who couldn't find
his way to the men's room without directions. Another, younger one
was so impressed with himself, it was impossible to have a
conversation with him without him saying, "When I was working on my

thesis..."

Pass him in the hall and say, "Nice day today."

He would reply, "Yes, it is but I remember a day back when I was working on my thesis..."

Sorry, "A bunch of IEEE PhD's" impresses me less than a handful of the guys posting here.

Poor choice of reading. It should have been extensive enough to
resolve your confusion.

>My choice, then, is to use the ground on the mains.

Not always the best choice, but all such considerations have issues.

>Given that the shield is earth grounded on the antenna and the equipment

You better believe it.

>Seems like a catch-22.
>
>My own gut says safety first, lower risk of RF issues after-the-fact by
>? what ?

You first have to figure out what ground means.

>I remember suggestions of coiling the ground wire in an RF choke,
>multiple ground lines of various lenghts to mess with harmonics.
>Ferrite beads? Chicken blood and a black cat?

Hi John,

A dipole certainly doesn't need a ground connection. Neither does a
choke or BalUn. The lightning arrestor - obviously. But you are not
going to do that through house wiring.... are you? No. So where?

Starting with that last point, the ground needs to be close by the
arrestor, and given the coax can be laid out anywhere, it may as well
pass nearby your service ground where you can provide a short ground
lead to the arrestor.

Then follows the possibility of the ground loop. This will only arise if the safety ground carries current (it shouldn't) or the neutral return to that service ground does, and has some resistance to boot. It stands to reason there will be current, what remains to be seen is if there is appreciable resistance (a poor connection).

Try as you might to avoid it, you WILL have a ground connection to the service ground from your rig (unless you are floating free on battery power and have absolutely no other accessories going to your rig). When you connect your arrestor to ground, this will guarantee a loop configuration. Any potential (pun intended) problem is strictly a matter of this resistance and current.

I'll cut it short with this as questions are sure to follow.

Hi Cecil

There is no reason to ever return any of the stuff I send out. I
actually enjoy knowing that someone appreciates this stuff. I dont pay $$
for it. It gets surplused by the government. My buddy buys it in bulk.
I am able to refurbish alot of the surplus he buys, like 100 KW gen-sets, so
he can re-sell the units back to them. Since I enjoy learning how to fix
the broken stuff, I dont charge for my time. So, he lets me sort thru his
"scrap piles". Everyone wins. But, I dont get to watch much TV because
I keep too busy learning how to fix the stuff.

Send me your shipping address. The HP 8405A will be in the mail within a
day after I get the address.

Do you have any use for a HP 8660 signal generator main frame, *no*
plug-ins? That would sure be a nice generator to go with a Vector
Voltmeter. I have 5 main frames but I havent been able to win an eBay bid
for the plug-ins.

Jerry

Once again this indicates you are not familiar or comfortable with basics, and have gotten ahead of yourself by going off somehwre in a land of reflected waves. Now you are confused, and can't make sense of basics.

The generator sees a reactive load. When the generator sees a reactive load, current and voltage are no longer in step. This is true all through the system from source to load.

> > 3.) You also claim significant current phase shift exists between the

Phase shift in what Cecil? This is how people get in trouble, make misstatements, and wind up blaming others for what they say. Here we are again, trying to work traveling and standing waves into a system too small to have anything stand when another significantly better analysis method would easily explain it all.

You keep trying to define the "inductor" in terms of degrees related to standing waves like standing waves change the properties of the component. I can't remember the last time I called to order an inductor and they vendor asked me "what phase shift in degrees of standing wave 100uH inductor do you want?".

> > It's very simple to measure current and voltage and the phase
> > relationships in a two terminal device and prove you are wrong.
>
> I've got many technical references that disagree. If you can do
> that, why haven't you done that?

I have done it and told you how, you ignore it. Roy has done it and told you how, you ignore it. I'm sure many thousands of people here and everywhere else understand in a reactive system voltage and current are not in phase. I'm equally sure many thousands of people, including lurkers here, understand a small inductor operated well below self-resonance has equal phase current entering one lead and leaving the other.

The only way to get confused on that is if someone doesn't understand
behavior of the basic component, gets in over his head and confuses
himself trying to use a tool that doesn't work, and then lashes out at
others and refuses to listen.

> > The current flowing into one end and out of the other end of a small

There you go again, back to the lowest form of debate. If you can't
understand something or get trapped, just call the other guy a liar.

You very clearly said current in each terminal of the inductor has a
different phase shift several times in your posts.

> > I say I can easily build a loading coil that acts the same way. I can

I can't understand what you are saying or what your point is, other
than you think I am being fooled by standing waves, I am ignorant, and
anything I measure is irrelevant.

Maybe someone else can help me with your last statement.

Maybe someone else on this group can explain or understand what you are trying to say.

Anyone help me here? What is Cecil saying in that last paragraph? What does the pattern of a radiating structure in the far-field have to do with current in a circuit with a reactor?

> Ferrite beads? Chicken blood and a black cat?

John,

You have been misled and confused by bad information.

Richard Clark has given you good advice.

The only antenna that requires an RF ground is an antenna with a single conductor feedline worked against ground, or an antenna that is poorly designed or constructed.

The only reasons to have a hamshack ground, unless you are trying to band-aid an antenna that is improperly constructed or feed a longwire, are electrical safety and lightning.

Electrical safety can be taken care of by using a three wire outlet with grounding to the sagfety ground, and by following national codes. National codes require your station ground be bonded to the power mains entrance ground. We are not suposed to have two isolated grounds according to NEC, and it is a bad idea to have isolated grounds for lightning, safety, and RFI reasons.

I'm afraid all the talk about ground loops and such have confused you.

Try reading this:

Thanks, Wes. When you say "lower frequencies", does that include
4 MHz?

> The instrument uses a phase-locked oscillator to drive the samplers
> with the "A" probe being the reference. One meter can be switched to

I was planning to use toroidal pickups and a Lissajous figure
for the phase measurement. Did you know "Lissajous figure"
is described in my 1957 ARRL Handbook but not in my 2000
ARRL Handbook?

My main concern is how to ensure there are no reflections
present during the measurement. I need to put the 75m
bugcatcher coil in an RF loop where current is flowing
in only one direction. That's easy to draw on paper but
I'm concerned about it. How would you set it up?

Have you looked at the articles on the web pages I posted?
Here's a funny quote, not previous quoted from:

http://www.ttr.com/corum/index.htm

"What frequency did you get in step 5? ... Is the difference
within engineering accuracy ... less than 5%? If the answer
is yes, then you may confidently use lumped-element modeling.
However, if the answer is no, then, from the halls of Valhalla,
old Wotan, himself, is thundering out over the battlements,
'#*@&%!! ... Thor, you dumdum! You CAN'T use lumped circuit
modeling!' ... [The coil has standing waves and is behaving
as a distributed resonator.]"

In case you missed it, here's what Walter Maxwell had to say
about the subject:

>> "If an inductance is in series with a line that has
>> reflections, the current will NOT be the same at both
>> ends of the inductor."
>>
>> "Consequently, circuit analysis will not work when both
>> forward and reflected currents are present in a lumped
>> circuit."

Cecil, I really think you should let Walt speak for himself. You have a history of distorting facts and taking statements out of context, and may be discrediting Walt. Walt is too nice a person for me to stand by and let that happen.

If anyone really thinks that as a stand-alone statement, it is not correct. I suspect he didn't get the full story or wasn't following a discussion closely, or you have snipped something out of context. It's very easy to take small areas out of context and make it seem like someone is saying something they are not.

Any circuit analysis will work so long as the load impedances used in the analysis are the same as the load impedances presented at that point by an antenna.

The behavior of any small two-terminal component REQUIRES currents to be essentially equal. It's only when the component has a third significant path to the outside world that currents can be unequal.

If I have a small capacitor, current flowing in one lead is equal to current flowing out the other and the phase of each current is exactly equal. Same for an inductor.

That's not a guess, that's a rule of how things always behave.

I'm wondering if the real problem is some people spend too much time with transmission lines and antenna and not enough time with circuit components, and become rusty?

In any event, you do enough damage to people's reputations Cecil. Please leave Walt alone. He will speak for himself if he likes.

2382. Dipole Extension

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-10 12:55:55 UTC
From: "Dick, AA5VU" <aa5vuNOSPAM@arrl.net>
Message-ID: <aa5vuNOSPAM-547450.06555410032006@newsclstr02.news.prodigy.com>
Source record: 63443

I have an old (but very good) W9INN 40/80 dipole. The only problem is it is cut for the upper phone band (centered at ~7.200) for 40 meters and I now do most operating in the lower portion of the band and would like to move the center to about 7.100 MHz. The 40 meter portion of the antenna is all soldered so I cannot just unwrap and extend it bit.

Any suggestions on the best way to add a extension and how much to add?

I have been thinking about cutting it and soldering in an X?-inch splice. Does the extension wire have to really match?

Dick AA5VU

I didn't ask or say anything about voltage. The fact that you
refuse to answer my technical questions speaks volumes.

>>Please define "compact" in terms of the number of degrees
>>of phase shift measured using a traveling wave.
>
> Phase shift in what Cecil?

The measured phase shift is in a traveling wave through a 75m
bugcatcher coil. How long does it take the traveling wave current
to flow from one end of the coil to the other? Your lumped-circuit
model presupposes instantaneous current flow for traveling waves.
Let's measure the current delay in a traveling wave to see
if your model is correct. If it is not correct, it is useless.

You cannot even begin to understand the problem if you don't
know that basic phase shift. I'm willing to bet that my 75m
bugcatcher coil has at least a 40 nanosecond delay on 4 MHz
which is a 60 degree current phase shift.

If that measured delay is in the ballpark of 40 nanoseconds
or more, it proves that your lumped-circuit model has failed
and your invalid proof is presupposed in the invalid model.

You cannot use a model that presupposes instantaneous current
flow to prove that the current flow is instantaneous. You cannot
use a model that presupposes constant current magnitude to prove

that the current has constant magnitude.

> You keep trying to define the "inductor" in terms of degrees related to
> standing waves ...

Not true, Tom, and just shows how confused you are about
what I have said. For the Nth time: The phase of the standing
wave current doesn't change up and down the entire length
of a 1/2WL thin dipole. Why would anyone expect it to change
at the ends of a loading coil? As far as I am concerned we
can drop any discussion of standing wave current phase. It is
meaningless. The phase that Roy measured was standing wave
phase. It was already known and is completely irrelevant. I
asked Roy to measure the traveling wave phase shift. He didn't.

> I have done it and told you how, you ignore it. Roy has done it and
> told you how, you ignore it.

You guys are measuring standing wave current that doesn't
flow and doesn't change phase. Your measurements are
completely meaningless and your flawed model has you
hoodwinked.

> The only way to get confused on that is if someone doesn't understand
> behavior of the basic component, gets in over his head and confuses
> himself trying to use a tool that doesn't work, and then lashes out at
> others and refuses to listen.

That's an exact description of you and your lumped circuit
analysis in a standing wave environment. Do you disagree with
Walter Maxwell?

> Walt wrote:
>> "If an inductance is in series with a line that has reflections,
>> the current will NOT be the same at both ends of the inductor."
>>
>> "Consequently, circuit analysis will not work when both forward
>> and reflected currents are present in a lumped circuit."

The component is not the problem, Tom. The problem seems to be
your feigning of total ignorance of the laws of reflection
physics in order to avoid discussing the real problem.

> There you go again! Back to traveling and standing waves.

Yes, you are never going to understand what I am saying about
standing-wave antennas until you discuss traveling and standing
waves on the standing-wave antenna. Your lumped-circuit model
is known to fail in the presence of standing waves.

> There you go again, back to the lowest form of debate. If you can't
> understand something or get trapped, just call the other guy a liar.

No, it's a lot simpler than that. When you lie about something
I said, I call you a liar.

> You very clearly said current in each terminal of the inductor has a
> different phase shift several times in your posts.

One more time. The standing wave current does NOT change phase
at the ends of the coil. The standing wave current essentially
does not change phase unless a dipole is longer than 1/2WL.
The phase of the standing wave current is totally irrelevant.

The forward traveling-wave current experiences a delay through
the coil. The reflected traveling-wave current experiences a
delay through the coil. This delay can be measured on the bench.
If the delay is not negligible, your lumped-circuit model is
useless because it presupposes a delay of zero.

> I can't understand what you are saying or what your point is, ...

Please don't insult my intelligence or yours. Every one of us
performed those experiments on the bench in college. Exactly
what is it about bench measuring the RF current delay through
a coil that you don't understand?

> Maybe someone else can help me with your last statement.

Do you even know what a standing wave current loop is?

> Maybe someone else on this group can explain or understand what you are
> trying to say.

You must have missed EE203. :-) What is it about a continuous
exchange of energy between the E-field and H-field at a fixed
point on an antenna wire that you don't understand? That's
just a characteristic of standing waves. Roy has used the
same argument in the past to try to prove that reflected
energy doesn't flow. But's it's the standing wave energy
that doesn't flow.

The fact you can't understand simple direct answers does the same. You asked how what I measured could happen, I answered. You either are choosing to ignore the answer becuase you don't like it, or you don't understand it.

When Roy measured current (and I did the same) using inductive coupling in a current trasformer, a method that requires a time-varying current to excite the secondary, you dismissed Roy's measurements with some odd response about him measuring current that doesn't flow.

I already measured the phase of current, and it is nearly zero degrees. It seems obvious to me that when someone gives you and answer you don't like, you either personally attack that persona and call them a liar or you make up some lame excuse like "you measured current that doesn't flow".

I don't know what others think, but it is starting to look to me like you either don't understand the basics of measurements or you are just unwilling to learn.

> You cannot even begin to understand the problem if you don't
> know that basic phase shift. I'm willing to bet that my 75m

> which is a 60 degree current phase shift.

I can measure that. My network analyzer measures time delays. The problem I see is if I take time from my busy schedule and measure it, you will either call me a liar or say I measured current that doesn't flow.

Before measuring anything specific I'm going to warn you that I've measured group delays many times before, and the group delay in an inductor is significantly less than the group delay in a transmission line of the same conductor length. I know that from past experience.

But if you promise to control yourself and not dismiss a measurement with personal attacks or insults, and promise to not do an about-face like you did with Roy and say "you really didn't measure current that moves with your thing that only measures changing current", I will do that.

I really wish some of your ideas were correct. If they were correct, I would not have thousands of feet of coaxial cables coiled under my bench. I would not be forcing customers to cut long delay lines when their equipment could just use a simple wound up piece of enameled wire.

> If that measured delay is in the ballpark of 40 nanoseconds

I understand it fine. I don't think the problem is on my end. If it is,
someone besides you will chime in and tell me. I'm afraid I don't trust
your opinions very much.

Those are Walt's exact words, not mine. If you don't believe me,
send him an email and ask him.

> The behavior of any small two-terminal component REQUIRES currents to
> be essentially equal. It's only when the component has a third
> significant path to the outside world that currents can be unequal.

Wrong! Wrong! Wrong! Your lumped-circuit model presupposes that
the currents are equal so you are begging the question. YOU
CANNOT USE YOUR MODEL TO PROVE ITS OWN PRESUPPOSITIONS. I see
you haven't yet read what Dr. Corum had to say on that subject.

http://www.ttr.com/corum/index.htm

> If I have a small capacitor, current flowing in one lead is equal to
> current flowing out the other and the phase of each current is exactly
> equal. Same for an inductor.

Sorry, that's just not true for inductors. In the real world,
there is a traveling wave current delay through the coil that
can easily be measured on the bench. That delay converts
directly to a phase delay. You are simply mistaken, hoodwinked

by your lumped-circuit model, which presupposes the proof of
what you say above. You are once again, begging the question
and assuming the proof without having proved anything.

> That's not a guess, that's a rule of how things always behave.

BS, Tom. That's a rule from a model known to fail in the
presence of standing waves. Models existing in your mind
don't dictate reality. It is supposed to be just the opposite.

> I'm wondering if the real problem is some people spend too much time
> with transmission lines and antenna and not enough time with circuit
> components, and become rusty?

The real problem is that you are looking for your keys under
the streetlight instead of in the dark where you lost them.

The real problem is that you are doing the same thing as the
naive ham who tries to measure feedpoint impedance with an
ohm-meter.

The real problem is that you are using a tool known to fail
under the conditions in which you are trying to use it.

THE LUMPED-CIRCUIT MODEL FAILS IN THE PRESENCE OF STANDING WAVES!
I know that. Walt knows that. Dr. Corum knows that. A number
of lurkers on this newsgroup know that. Nikola Tesla obviously
knew that in his 1897 patent application.

> In any event, you do enough damage to people's reputations Cecil.
> Please leave Walt alone. He will speak for himself if he likes.

Please mind your own business. I have Walt's permission to
quote his stuff. If he ever asks me to stop quoting him, I will.
One wonders if your attitude would be different if Walt agreed
with you? :-)

Hi Y'all! (said with a strange Australian accent!)

Am doing so NEC work for my QTH and need to get an idea of the ground conditions here.

I started with the "Rich soil" of Dallas>Lincoln but was advised that it was more clay and likely to be typical of that in central VA.

Any information helpful.

Cheers Bob W5/VK2YQA

The 4NEC2 manual extract is attached inline below;

Pastoral, low hills, rich soil, typical from
Dallas, TX, to Lincoln, NE 0.0303 20 Very Good

Pastoral, low hills, rich soil, typical of OH
and IL 0.01 14 Good

Flat country, marshy, densely wooded, typical
of LA near the Mississippi River 0.0075 12

Pastoral, medium hills, and forestation, typical
of MD, PA, NY (exclusive of mountains and
coastline) 0.006 13

Pastoral, medium hills, and forestation, heavy
clay soils, typical of central VA 0.005 13 Average

Rocky soil, steep hills, typically mountainous 0.002 12-14 Poor

Sandy, dry, flat, coastal 0.002 10

When I wrote last, I was nursing a big toe that had just suffered the trauma of having a 4' x 8' sheet of 3/4" plywood dropped on it edge on. So I didn't want to hobble into the shack to search for the manual.

Now I have it before me. The nominal impedance of the probes is 100 Kohm shunted by 2.5 pF. If this doesn't upset your measurement then you're good to go.

I think that when I was remembering probing circuits with the bare probes I was thinking of the HP Vector Impedance Meter more than the VVM. It was a lower frequency instrument designed for that purpose.

What Cecil needs to do is bias the coil with a DC bias current that
safely exceeds the peak RF current.

Then he would have RF current flowing in only one direction.

I am not familiar with your 40/80 dipole, I assume it is a trap
arrangement.

The 1/2 wave difference on 40M of 7.2 and 7.1mhz is only about a foot.
The change in a DIPOLE at 40M would be difficult to measure.

I would not change it.
Do you have an indication that it needs adjustment?

I've added extensions via an alligator clip with a piece of wire
attached, and then shorten that wire until you get a good match.

Bob, According to my 1977 edition of "Reference Data for Radio Engineers"
Soil conductivity along the south bank of the red river is 30mS/m (Most of
the OK side is shown as 15 mS/m). Since the map is not very detailed, and
without going to the extent of graphic overlays, it seems that Dallas is in
a region of lower conductivity at 15 mS/m. If you are interested I can scan

the map for you.

I went to the trouble of measuring my soil conductivity; using the "4 rod method", with 60 Hz AC, as per the ARRL handbook (Measured 52 mS/m in Calgary). I believe I have JPEGs of the relevant pages someplace. Also some guys I was working with, a couple of years ago, devised a method of measuring the complex permittivity with a capacitor structure. There were some problems with the method, which they eventually corrected. The information was required to analyze short range VHF transmission underground.

<w8ji@akorn.net> wrote:
> The fact you can't understand simple direct answers does the same.

I love simple answers, Tom. What I don't like are simple-minded
answers based on an invalid model.

> When Roy measured current (and I did the same) using inductive coupling
> in a current trasformer, a method that requires a time-varying current
> to excite the secondary, you dismissed Roy's measurements with some odd
> response about him measuring current that doesn't flow.

The inductive coupling does NOT require a time-varying
current. All it requires is a time-varying H-field. That
standing wave H-field is indeed varying but it's not because
current is moving laterally up or down the wire. That H-field is
fixed at a point on the line exchanging energy with the E-field
which is also fixed at the same point. If the H-field is not
moving laterally up or down the wire (it isn't) then the current
is NOT flowing. You must have missed that day in your
fields and waves class.

Take a metal rod. Slip a string through a washer and tie it.
Loop the string onto the metal rod. Put a grommet on the
rod on each side of the string to keep it in one place in
the X dimension on the wire. Now, keeping the X dimension
fixed, swing the loop in the plane of the Y and Z dimensions
and look at it on edge. You are looking at a physical analogy
of the standing wave current at a point on a wire. Is the
string moving? Not in the X dimension which is constant
and fixed by the grommets.

At any point on a wire with standing waves, the E-field
and H-field are not moving laterally up and down the wire. They
are *stationary* at a point on the wire. All that is happening at
that point is the E-field and H-field are swapping energy at the
RF frequency. The current probe naturally picks up those
stationary oscillating fields. You and Roy still don't understand
what it was that was being measured.The current that you and
Roy measured was not flowing. It was just standing there.
That's why they call it a *standing* wave. The currents
that are required to be constant through the coil are the
traveling-wave currents.

A standing wave is not at all a wave in the classic definition
of EM waves. It is simply a superposition of two classic EM
waves flowing in opposite directions. Here's an optical example

of what is happening to you. The yellow light coming from your
TV is an interference pattern between red, blue, and green
light. You are measuring yellow light thinking that's a primary
color. It is not. But you could use your yellow light measurement
to estimate the strength of the primary colors.

The standing-wave current is an interference pattern caused
by superposition of forward and reflected current waves.
Like the yellow light you are seeing, it is not primary, and
like the yellow light, it is an artifact of interference..

In a wire in which one amp is flowing in one direction and one
amp is flowing in the opposite direction, there is no net flow
of current. Therefore, standing wave current has no net flow.
That is obvious from its constant, fixed phase angle which
doesn't change (much).

> I already measured the phase of current, and it is nearly zero degrees.

The measured phase of the net standing wave current is near
zero degrees whether a coil exists or not. All it means is that
the net standing wave current is standing still. Basing your
conclusions upon measurements of a current that is not even
flowing is foolish.

> I don't know what others think, but it is starting to look to me like
> you either don't understand the basics of measurements or you are just
> unwilling to learn.

You have been seduced by your model that is known to fail in the
presence of standing waves. Why you cling to such a false prophet
in the real world is beyond me.

> I can measure that. My network analyzer measures time delays. The
> problem I see is if I take time from my busy schedule and measure it,
> you will either call me a liar or say I measured current that doesn't
> flow.

If you measure a traveling wave current, you will be measuring a
current that is actually flowing. Your S12 phase shift measurement
showed a -60 to -70 degree phase shift in a 100uH coil at one
MHz. That measurement of yours has already proved that your
lumped-circuit model is invalid. Why didn't you just use the
zero degrees predicted by the lumped-circuit model instead
of measuring it? :-)

> Before measuring anything specific I'm going to warn you that I've
> measured group delays many times before, and the group delay in an
> inductor is significantly less than the group delay in a transmission
> line of the same conductor length. I know that from past experience.

I know that, Tom. The point is: If there is any appreciable delay
through the coil, that fact violates the presuppositions of the lumped-

circuit model. Therefore, a lumped-circuit model cannot be used
to explain the characteristics of that real-world coil and especially
not in a standing wave environment.

> But if you promise to control yourself and not dismiss a measurement
> with personal attacks or insults, and promise to not do an about-face
> like you did with Roy and say "you really didn't measure current that
> moves with your thing that only measures changing current", I will do
> that.

I appreciate that and I would also appreciate it if you didn't pencil
whip the results before reporting them. Please just be honest. I
assume we are both after the truth. And be sure to measure a
coil something of the size of a 75m bugcatcher coil. I think a
75m bugcatcher coil would show more of a delay than a
toroidal inductor of the same inductive reactance.

> I really wish some of your ideas were correct. If they were correct, I
> would not have thousands of feet of coaxial cables coiled under my
> bench. I would not be forcing customers to cut long delay lines when
> their equipment could just use a simple wound up piece of enameled
> wire.

Surely, you are familiar with helical transmision lines with a very,
very small velocity factor. And Intel does use simple coils as delay
lines in some of their PCB designs.

> Does ANYONE on this newsgroup understand Cecil? I need help here.

They are there, Tom. But they just don't want to tangle with a junk
yard dog. Most people don't have a thick enough skin to withstand
your onslaughts. I get a couple of emails a week from those guys.
One distinguished gentleman and well known ham said that you have
never lost an argument, even when you were wrong. I know exactly
what he means.

> What a silly statement. We are measuring a time-varying current that
> doesn't flow or change!

It's magnitude changes but it indeed doesn't flow or change phase.
It's magnitude changes because the E-field and H-field are continuously
exchanging energy at the frequency of operation. If you understood the
implications of a constant, fixed, unchanging phase, you would know
that.

> Yes, if he wrote what you quoted and you didn't lift something out of
> context I totally disagree with him.

So be it.

> > Your lumped-circuit model
> > is known to fail in the presence of standing waves.
>
> Nonsense.

YOUR LUMPED-CIRCUIT MODEL IS KNOWN TO FAIL
IN THE PRESENCE OF STANDING WAVES!

What is it about that statement that you don't understand? Your lumped-circuit model presupposes conditions that don't exist in a standing wave environment. Therefore, it is invalid and another more powerful model must be chosen.Because your chosen model is invalid, the validity of everything you say is questionable.

The lumped-circuit model is a subset of the distributed-network model. The distributed-network model is a subset of Maxwell's equations. If you don't understand the limitations of the model, you will choose to use it under the wrong circumstances. That's what you, Roy, and others have done.

That is incorrect for the conditions we are outlining, and it is misleading Cecil. It has him lost in a world of reflections. You have gone outside the limits of the model by assuming, incorrectly, the inductor has no or little flux linkage from end-to-end and has large stray capacitance to the outside world compared to load impedance. The conductor used to build a inductor does not have current slowly winding its way along that path.

There is no virtually no difference in phase delay in current at each end of a relatively compact inductor. It is very easy to measure that. It also have very little group delay compared to the group delay one would expect from a transmission line or antenna the same length. I know that because I have measured it hundreds of times.

> I have repeated a url below that Cecil posted on the rraa. The material in that
> url agrees with my position, and specifically states that circuit analysis is

> who disbelieves this has forgotten the warning about the situation given in
> sophmore EE courses.

The Tesla coil, by definition of how it works, violates all boundaries of the examples myself and others are giving Cecil. It does not apply to the discussion at all.

The Tesla coil is intentionally of exceptionally long form factor. It has virtually an open circuit at the end, and is by operation self-resonant at the operating frequency. It has a very large amount of distributed capacitance compared to termination impedance, since the termination is an open. It is not operated at a fraction of self-resonance as people SHOULD know a good mobile loading coil is.

It has no bearing at all on the discussion, any more than it would if I started measuring the plate choke from an AL1200 amplifier at the self-resonant frequency with an open termination, or a loading coil for a 75 meter antenna at the self-resonant frequency.

Everyone (except Cecil) has been very careful to give the boundaries and describe the effects. The Tesla coil does not fit the boundaries described, and the secondary inductor in the Tesla coil behaves nothing

like an inductor operated well below self resonance.

> http://www.ttr.com/corum/index.htm

The very first paragraph of that reference should have been a red flag that it does not apply to this discussion. Here is what it says:

"Can one model the physical operation of a Tesla coil appropriately with only lumped-element circuits? If not, why not? It was pointed out long ago that, at its operating frequency, a Tesla coil is NOT a lumped-element induction coil. Forget the quest for "many turns of fine wire". In fact, a Tesla coil has more in common with a cavity resonator than it does with a conventional inductor."

The key words they use, and they even drew attention to the words by a type style change, "at its operating frequency, a Tesla coil is NOT a lumped-element induction coil". They were very clear about that, and go on to describe how it does behave like a normal induction coil.

Everyone in the conversation has been very careful to clearly establish the boundary conditions that the behavior we are talking about is significantly below self-resonance, an inductor of compact form factor, and an inductor of good design.

I can't understand why anyone would attempt to reference an article that, in the very opening, states the inductor is operating at self-resonance! I can't understand why anyone would reference an article that violates the boundaries of termination impedance outlined in the discussion, where it has been stated over and over again the inductor must be terminated in an impedance that is low compared to leakage impedances.

I can't imagine anyone using a lossy Tesla coil as an antenna or part of an antenna system. Please read the opening paragraphs of the article you reference.

It's a shame Bill is gone.
Not to worry. It should work just fine as-is. Mine resonates on 7.1 and works just fine on the whole band.

However, if you insist...Nothing special about extending. Just about any wire will work. The most important things to use a mechanical technique suitable for the job and it won't hurt to use a wire of similar gauge. Insulation is irrelevant.

Use the dipole formula 468/f(Mhz) to figure out the difference. Run the formula for the freq it is cut for, then for the freq you want and subtract (and divide by 2) to get the amount you need to add to each end. (or just use 234/f for the amount to add on each end).

As a double check, with Excel I get 5.49295774647888 inches on each end...
Cut very carefully!

That's about 5 and 31.5492957746483 / 64ths inches. (:-)

I think a lot of the contention on this subject is based on little more than such multiple meanings for common term, "current".

When you talk about current flowing, you seem to be thinking of current waves traveling along a conductor. Others seem to be saying "current" and thinking of charge movement. I think that only the second is technically correct (current is the movement of charge, not the traveling wave or standing wave pattern in that movement), but I think I understand what you are picturing. We switch to the short hand concept of calling a pattern of current changes a current every time we make an AC current measurement and refer to it as a non zero value, as we do with amperes (RMS).

Standing waves involve no net wave travel in either direction, though anywhere except at the current nodes, charge is certainly moving back and forth along the conductor, during a cycle. Thus, there certainly are instantaneous currents in both directions (depending on location and instant) along any conductor sustaining a standing wave, everywhere, except at the current nodes. And everywhere, except at voltage nodes, half way between current nodes, charge is piling up (as electrons move toward every other current node) and spreading out as electrons moves away from the remaining current nodes) creating voltage changes.

Traveling waves have a very similar charge movement as that which takes place half way between the nodes and peaks of the standing wave pattern. But there are no nodes or peaks, so the current swings between the same 2 values, everywhere along the conductor. Charge arrives from one direction, instead of from both directions and leaves in the other direction, each half cycle. Every other half cycle, the directions of arrival and departure reverse, even though the wave always moves in one direction. I am talking about conduction in wire, not EM waves in space, here.

This current (movement of charge in either a standing wave or a traveling wave) creates H field and the changes in that H field can be monitored with a current transformer. But at any single point, current measured with a current transformer has no way of knowing if the current changes seen are the result of a standing wave or a traveling wave. In both cases, charge is seen to be moving in alternating directions. But if you slide the current transformer along the conductor, the current magnitude will vary if standing waves are responsible for the current, and remain, essentially constant, if traveling waves are its source.

I apologize for stating the painfully obvious, but when basic terminology is the cause of misunderstanding, it sometimes helps to back up a step in the direction of a more basic view to uncover the origin of the misunderstanding.

What is causing the misleading part is: THE LUMPED-CIRCUIT
MODEL FAILS IN THE PRESENCE OF STANDING WAVES!

> There is no virtually no difference in phase delay in current at each
> end of a relatively compact inductor.

Is a 75m bugcatcher coil a "relatively compact indictor"? If you say
yes, you are stuck with its measured delay. If you say no, then we
are not discussing the typical amateur radio mobile loading coil.

Of course, one turn on a toroid is going to exhibit the characteristics
you are presenting. But that is not a typical bugcatcher coil either.

> The Tesla coil, by definition of how it works, violates all boundaries
> of the examples myself and others are giving Cecil. It does not apply
> to the discussion at all.

False: A 75m bugcatcher coil used as a 1/4WL resonator on
9-10 MHz meets the minimum requirements for a Tesla coil.
It uses 1/6 wavelength of wire on 75m. I'll bet it would
certainly arc at a kilowatt.

The typical minimum Tesla system is a coil with a top hat sphere.
It looks a lot like your 160m mobile antenna. :-)

> It is not operated at a fraction of
> self-resonance as people SHOULD know a good mobile loading coil is.

A 75m bugcatcher coil is operating close enough to its self-resonant
frequency that the self-resonant effects are certainly present.

A 75m bugcatcher coil can be considered to be a lumped circuit
impedance at 60 Hz but certainly not at 4000000 Hz. In fact,
that is the whole question. At what frequency can the lumped
circuit model be validly used on a 75m bugcatcher coil? I'm
willing to bet that frequency is lower than 1000000 Hz.

> It has no bearing at all on the discussion, ...

Wishful thinking on your part.
.
> In fact, a Tesla coil has more in common with a cavity resonator

A 75m bugcatcher coil has more in common with a cavity resonator
than it does with your lumped circuit inductance.

> "at its operating frequency, a Tesla coil is NOT a
> lumped-element induction coil".

Neither is a 75m bugcatcher coil.

> Everyone in the conversation has been very careful to clearly establish
> the boundary conditions that the behavior we are talking about is
> significantly below self-resonance, an inductor of compact form factor,
> and an inductor of good design.

A 75m bugcatcher coil used on 4 MHz is NOT significantly below
the self-resonant frequency of 9-10 MHz.

THE LUMPED-CIRCUIT MODEL FAILS IN A STANDING
WAVE ENVIRONMENT! In the face of that simple technical fact,
all other discussion is moot. Anyone wishing to validly model a
75m bugcatcher coil used on a mobile antenna is forced to choose
a model that does not presuppose faster than light wave travel
through a 75m bugcatcher coil. It's as simple as that.

Tom, with a straight face, I want you to assert that the RF waves
on a 75m bugcatcher mobile antenna are traveling faster than
the speed of light. If it takes 125 nanoseconds for the forward
current wave to make it from the end of the antenna and back
to the feedpoint, then the lumped-circuit model yields invalid
results. TDR anyone?

(snip)

Real world inductors cover a wide range of construction from tiny
(with respect to wavelength) units that have tight flux linkage
between all turns, to extended things that fade into slow wave, high
inductance transmission lines (think of a straight conductor with
ferrite beads strung on it. Any discussion of inductors and waves
needs to either select an example inductor for discussion, or remain
general enough to cover anything that might be called an inductor.

Or else, endless and pointless arguments will ensue.

Yes it is, but no so far as to have perfectly equal currents at each end an zero phase shift in current. It is in the neither land between a Tesla coil (which is still nothing like my mobile antenna, but at least getting closer) and a idealized lumped component.

Nonsense. You are ignoring the coupling mechanisim inside the inductor.

They are not travelling faster than light.

What you (and the one or two others who seem to agree with you) repeatedly ignore or forget is magnetic flux couples one turn to another. A real inductor is always someplace between the two extremes of something like a radial mode helice (helically loaded whip) and an ideal lumped component.

Since you have taken the path of totally forgetting or ignoring flux coupling, you are reaching incorrect conclusions. Using the Tesla coil model is a good example.

Everyone is freely admitting there is *some* transmission line effect going on. There is some distrbuted component (a series of inductors shunted by capacitors) going on.

Everyone (except you) is being careful to qualify remarks by specifying the inductor is operating well below self-resonance.

If you weren't so pig-headed you could look at the measured data at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

...and see that as inductors move towards self-resonance they do begin to display characteristics of transmission lines.

It's too bad in three years you have claimed others made a measurement error, when in fact the error is in thinking all of the current in a loading coil slowly winds its way around turn by turn and the magnetic field linking turns does not cause charges in other turns to move long before current traveleing at light speed would wind through the copper path.

Until you stop, put the beer away, and think about this a while you'll continue to butt your head up against people who KNOW how inductors behave.

That's about a 99% change in attitude from when we started this
discussion a couple of years ago. At that time you were claiming
that a 75m bugcatcher coil modeled as a lumped inductance with
EZNEC showed zero change in current magnitude and phase and that
was that. I'm glad to see the truth winning for a change.

I think you are going to have to go a *LOT* lower in frequency
than 4000000 Hz before a 75m bugcatcher coil can be treated as
a lumped-inductance.

>>THE LUMPED-CIRCUIT MODEL FAILS IN A STANDING

>
> Nonsense. You are ignoring the coupling mechanisim inside the inductor.

That coupling mechanism works, at best, a lot
lower than the speed of light and only on the voltage. In
a high-Q inductor, the current is known to lag the voltage
by a phase angle approaching 90 degrees. Do you have any
idea what the velocity factor of a 75m bugcatcher coil is?
I'll bet Reg can tell us.

If the voltage is indeed traveling at the speed of light, the
current is known to lag the voltage by a large number of degrees
approaching 90 degrees for an ideal coil. The laws of physics
strikes again. How can you bring yourself to ignore them? The
voltage cannot travel faster than the speed of light and the
current is lagging by, e.g. 60 degrees. It's hard not to suffer
a 40 nS current wave delay through the coil on 4 MHz. I've told
this to you before but you have avoided the subject like a plague.

> What you (and the one or two others who seem to agree with you)
> repeatedly ignore or forget is magnetic flux couples one turn to
> another. A real inductor is always someplace between the two extremes
> of something like a radial mode helice (helically loaded whip) and an

You are talking about the E-field, not the H-field. I can agree with
the E-field propagating at the speed of light but the H-field is
known to lag the E-field by an angle approaching 90 degrees in the
limit for an ideal inductor. Or is that another law of physics that
you simply choose to ignore?

> Everyone is freely admitting there is *some* transmission line effect
> going on. There is some distrbuted component (a series of inductors
> shunted by capacitors) going on.

Are you admitting that a 75m bugcatcher coil can be modeled as a
transmission line with a Z0 and a VF? If so, you are giving up
on your lumped-constant model. Actually, since the lumped-constant
model is a subset of the distributed-network model, the lumped-
constant model is very often wrong when the distributed-network
model is correct. OTOH, it is impossible for the lumped-constant
analysis to be right while the distributed-network analysis is
wrong. So much for your choice of models.

> Everyone (except you) is being careful to qualify remarks by specifying
> the inductor is operating well below self-resonance.

A 75m bugcatcher coil is NOT operating "well below" self-resonance.
It is operating at 1/2 the self-resonant frequency. If one adds one
foot at a time to the stinger above a 75m bugcatcher coil, at exactly
what frequency does it cease to act like a "velocity inhibited
slow-wave helical" and start acting like a lumped inductance? I
propose that frequency is considerably lower than 1000000 Hz.

> If you weren't so pig-headed you could look at the measured data at:
> http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

You measured standing wave current, Tom. Your measurements are
meaningless! Standing wave current has the same constant phase
whether the coil exists or not. Your measurements prove absolutely
nothing that is not already known.

> Do you have an indication that it needs adjustment?

John,

When i trimmed it the first time (years ago) I was working mostly SSB so it is great in phone band and okay in the old Novice portion. I am now working mostly 40 meter RTTY and PSK and these are at 7.070 and 7.035.

The current antenna shows SWR of about 1:8 at 7.100 and goes up to 2:0 at 7.050. My TS-570S tuner makes the rig smile but I feel it would be better if I could extend it a bit.

The problem is there is no wrapped back wire that I could let out and hate to use a jumper extender at the loading coil.

I may have to just bit the bullet and cut some wire per the formulas by Steve, K9DCI, and solder it in the middle some place.

Still thinking about it. The WX in South Texas is too nice for antenna work. I will probably put it off until the WX is bad.

I am not familair with this antenna, but if it has a choke/trap for 40M,
just add a foot of wire on the side of the choke/trap that is closest to the
center insulator- let it hang down and dangle. You can clip it on as one
poster said- this is a high Z point and contact resistance is a non-issue.
But as others have said, the on-air difference is zero.

Nothing I have said has changed from what I've said for years.

Now you have magnetic fields traveling slower than light speed in air,
and have gone right back to the same nonsense of standing wave current.

Please tell us all how you would measure the "traveling current" while
ignoring "standing wave current".

This ought to be good.....

2413. Re: Current through coils

w8ji@akorn.net wrote:
> Please tell us all how you would measure the "traveling current" while
> ignoring "standing wave current".

Good question. One would ideally do it in a system without
reflections. I am struggling with that concept right now.

The best thought I have come up with so far is simple:

```
coil
+----////----+
| |
source --- cap
| ---
| |
+--/\/\/\/\--+
resistor
```

I'm not a measurements guy so I could use some help.

What's wrong with just reporting the measured the delay
through your test coils? Your measured data already
shows the current on one side of the coil to be
different from the current on the other side of the
coil. All we have to worry about now is the delay
through the coils.

If I've got your attention, let me repeat something I
posted days ago.

The forward current through the coil can indeed be assumed
to be equal magnitude at both ends of the coil without much
error. That should make you happy.

The delay through the coil is whatever it is but it is
nowhere near zero. I assume that makes you unhappy.

The reflected current through the coil can indeed be
assumed to be equal magnitude at both ends of the coil
without much error. That should make you happy.

The delay through the coil is whatever it is but it is
nowhere near zero. I assume that makes you unhappy.

The standing wave is the phasor sum of the forward wave
and reflected wave. Its magnitude can vary from about
double the forward current at a current loop to close to
zero at a current node. I assume that makes you unhappy.

The standing wave phase is close to constant and fixed
near zero degrees within 1/4WL of the feedpoint. I assume
that makes you happy.

So three out of six results should make you happy and
that's about all any mere mortal can hope for. :-)

Hi

I would appreciate a review of the ScrewDriver antenna article in the February 2006 issue of Antennex.

1. Is it a full construction article?
2. If #1 is true, can the antenna as described be built from easily obtainable components and buit with a resonable toolset?
3. any other comments you would care to share

Thanks in advance to all for their consideration.

I agree on the part about the wx.
I doubt the antenna is really centered on 7.2 if it is up to 2:1 at 7.050. IF I were going to try to change anything, I would go to the hardware store electrical department and get a couple of screw type wire splices that are intended to splice about 12 ga. wire. Get the type that come apart so that you don't have to cut the antenna to string them on the wire. Alligator clips don't weather well here. You can add a foot on each end of the 40M section and trim from there. I hope the antenna goes up & down easy!

I would keep tabs on what is happening to the 80M operation as I went. The environment around the antenna (height above ground, quality of ground) may lead to erratic measurements. 2:1 is not a bad SWR. Your ability to tune it out fixes everything except the losses in the tuner and I doubt if they are high enough to consider!

Before you take any advice from me remember I consider myself an antenna student, not an expert!

John, many thanks for some rationality from a cool head.

Conventions aside, that sounds about right. So would you agree
that if there's a forward current of one amp and a reflected
current of one amp, the net charge movement is zero and therefore
the standing wave current is not "going" anywhere? How can something
with a constant fixed phase angle of zero degrees "go" anywhere?

That's unclear to me. Why can't the E-field and H-field simply be
exchanging energy at a point rather than any net charge moving
laterally?

Hi Ed, they ran an article on a Screwdriver 4 or 5 years ago but it was not a full construction as one would see in QST. Antennex does not usually give full construction details, they want you to experiment. That also keeps the cost of the articles down. As I remember the copper fingers are the most difficult to obtain.

Whether it can be easily built, you may have to do like I am considering, suscribe.
Good Luck.

Cecil,

I think I said all of that before the fun and games started. In any case I agree 100% with John.

Let me try again to answer your question. This is all very basic textbook stuff. I claim not the slightest bit of credit for any of this.

First, I hope we can agree that current is defined as the movement of charge. In this case the charge moves only in the direction of the wire, let's call it the z-direction.

The generic equation for a forward traveling wave is simply:

y = A cos (kz-wt)

The generic equation for a reverse traveling wave is:

y = B cos (kz+wt)

One can add constant phase offsets to the cosine arguments, but it does not make any difference here. It just makes things look messy, especially in ASCII. The parameters k and w are not independent either, but again that does not really matter here.

In the case of current we can say:

If = Io cos (kz-wt)
Ir = Io cos (kz+wt)

I have set the "A" and "B" coefficients to the same value, Io, for simplicity. If the currents are not the same the math gets a little messier, but there is no fundamental difference. Keep in mind that the If and Ir refer to the current that moves along the z-direction, i.e., charge moving in the back-and-forth direction along the wire. The "f" refers to the forward "wave", and the "r" refers to the reverse "wave". The current in both cases is not "forward" or "reverse" but simply back-and-forth as in any AC condition. It is essential to separate the concepts of wave and current. They may be connected, but they are not the same, and they are not interchangeable.

OK, now lets add these two traveling waves together to make a standing wave. This is a linear system, and superposition applies. We can simply add the components. The basic equation is:

Isw = If + Ir = Io { cos (kz-wt) + cos (kz+wt) }

Through the use of a standard trigonometric identity this can be reduced to:

Isw = 2Io cos (kz) cos (wt)

What can be seen immediately is that the standing wave current still has exactly the same time dependence that the traveling waves had. The magnitude of the current is now a function of z, unlike the constant magnitude in the traveling waves. The "current" is still defined as above, namely the charge that moves back-and-forth in the z-direction.

The current oscillation factor (wt) is now decoupled from "z", unlike the traveling wave case. The "wave" is stationary. The current itself, however, behaves exactly the same as in the case of the traveling waves.

Of course there are important differences in radiation patterns for traveling waves and standing waves. The magnitude of the current is different along the wire. However, except at the standing wave nodes, the standing wave current is very real and non-zero.

I am almost embarrassed to write this, since surely you and most readers know all of this quite thoroughly. However, it appears you may have overlooked something. I hope this helps.

73,
Gene
W4SZ

2420. Re: Current through coils

Source record: 63381

And, of course, since the net current is a function of distance along the wire, it follows that in the case Gene described, charge in each section of wire goes through a cyclic, sinusoidal increase and decrease. In other words, the wire exhibits capacitance. See Reg's second sentence in the posting that started this whole set of insanity off. (One might call the current Reg mentions in the third sentence "displacement current" as is often done.) Yawn. (It's kind of fun to look at an animation of the case where the magnitude of If and Ir are not equal. It's pretty straightforward to program in Matlab or Scilab.)

Cheers,
Tom

At great risk, let me try this approach.

I have a 100 turn 2" diameter #18 gauge wire air core inductor. There are 100 turns, so there is about 630 inches or 32 feet of wire in the coil.

I have a Network Analyzer with port to port time delay measurement capability. It measures coaxial cables very well, and even clip leads.

Cecil, please predict or guess the group delay of this inductor at 3.8 MHz. Tell us all what that group delay means for your wave theory.

Just come close, and I will tell you what it measures. I can even print the plot just for you.

That one on your web site measured the standing wave
current. We know the phase of the standing wave current
is irrelevent since it is essentially the same whether
the coil is in or out of the circuit. i.e. there is
no such thing as standing wave current "delay" since
the phase of the standing wave current is essentially
fixed at (or near) zero degrees.

You have measured the S12 delay for 100uH at 1 MHz to
be -60 to -70 degrees. What we need is the equivalent
of the S12 delay for current, rather than for voltage.
What is the current delay througn the coil when no
reflections are present? In other words, if the coil
were installed in a traveling-wave antenna, like a
terminated rhombic, what would the delay be through
the coil?

By this I assume you mean a traveling current wave with an RMS value
of 1 amp.

> and a reflected current of one amp,

Meaning a returning current wave with an RMS current of 1 amp.

> the net charge movement is zero and therefore
> the standing wave current is not "going" anywhere?

Sorry, no. There is no net (average over one cycle) current, whether
the wave is traveling or standing. In both cases the instantaneous
current changes direction every half cycle at any given point. If
there is a standing wave made of a 1 ampere RMS current wave and a 1
ampere RMS returning wave, then the standing wave current will vary
from zero amperes RMS at current nodes to 2 amperes RMS at current
peaks. Looking just at just current, and at only a single point, a
traveling current wave and a standing current wave are
indistinguishable. You cannot tell if the measured RMS current is
made up of a wave traveling in one direction, or the sum of two waves
traveling in opposite directions.

> How can something with a constant fixed phase angle of zero degrees "go" anywhere?

The only way to understand a standing wave having a phase of zero
degrees, that makes sense to me, is that it applies to all points
between one current node and the next. The points between the next
two nodes have a phase of 180 degrees (charge is moving in the
opposite direction at all times) with respect to the points between
the first two nodes. So, if you pick some point between a pair of
current nodes, all other points along the standing wave must be either
be in phase with the current at that point, or 180 degrees out of

phase with it. In a standing wave, charge sloshes back and forth in
opposite directions between alternate pairs of current nodes.
Likewise, where the charge piles up and sinks (at the current nodes),
voltage peaks occur because of the charge accumulation or shortage.

>> Standing waves involve no net wave travel in either direction, though

In an isolated EM plane wave, I think this is the case, and
displacement charge in space takes the place of conductor current.
But when a wave is guided by a conductor, we can measure the charge
sloshing back and forth in the conductor in response to those fields.

Take a look at:
http://galileo.phys.virginia.edu/classes/109N/more_stuff/Maxwell_Eq.html
about half way down.

Here is an excerpt:

(begin excerpt)

"Displacement Current"

Maxwell referred to the second term on the right hand side, the
changing electric field term, as the "displacement current". This was
an analogy with a dielectric material. If a dielectric material is
placed in an electric field, the molecules are distorted, their
positive charges moving slightly to the right, say, the negative
charges slightly to the left. Now consider what happens to a
dielectric in an increasing electric field. The positive charges will
be displaced to the right by a continuously increasing distance, so,
as long as the electric field is increasing in strength, these charges
are moving: there is actually a displacement current. (Meanwhile, the
negative charges are moving the other way, but that is a current in
the same direction, so adds to the effect of the positive charges'
motion.) Maxwell's picture of the vacuum, the aether, was that it too
had dielectric properties somehow, so he pictured a similar motion of
charge in the vacuum to that we have just described in the dielectric.
This is why the changing electric field term is often called the
"displacement current", and in Ampere's law (generalized) is just
added to the real current, to give Maxwell's fourth -- and final --
equation.

(end excerpt)

Cecil,

Earlier you made comments about the time delay through a 75 meter loading inductor being somewhere around 60 nS or so.

You have consistently disagreed with me when I said time delay through an inductor with tight mutual coupling from turn-to-turn is somewhat close to light speed over the physical length of the inductor, rather than the time it takes current to wind its way around through the copper. You didn't like my measurement of a small 100uH choke, and said a large inductor like a bug catcher coil is different. You predicted standing waves in that inductor.

I have a 100 turn 2 inch diameter air wound inductor of pretty good quality. It is 10 inches long.

Please tell all of us the time delay you expect in that inductor on 3.8 MHz. Please tell all of us what that delay means for your various changing theories about waves standing in that coil.

I'll sweep the inductor from below the BC band up to 30MHz in a time measurement mode and post the printout of the sweep with scale values and markers that show time delays.

Frank,

The measurement method in the Handbook is seriously flawed. You will
almost always measure something many times better than the soil really
is at radio frequencies.

Since soil conductivity varies widely over small distances, and since
it also has seasonal variations, a rough guess from a book is about as
good as anything.

Myself, I don't worry about it. I just use average soil in models.

On the contrary, when kz is not linked by a plus or minus sign
to wt, the wave doesn't move anymore. Maybe you need a review?

Gene, you are a genius. Why didn't I think of that? I recognize
that equation from "Optics", by Hecht. Pick any point, 'z', and
see what you get. Hecht says, "It doesn't rotate at all, and the
resultant wave it represents *DOESN'T PROGRESS THROUGH SPACE* - it's
a standing wave." The RF equivalent of a standing wave of light that
doesn't progress through space is an RF standing wave that doesn't
progress through a wire. That's what I have been telling you guys.
Standing waves don't move. Standing wave current doesn't flow!
Even in empty space, a light standing wave doesn't progress
through space, i.e. IT DOESN'T MOVE!
That is on page 289 of "Optics", by Hecht, 4th edition.

From "Fields and Waves ...", by Ramo & Whinnery, in describing the
standing wave situation: "The total energy in any length of line
a multiple of a quarter wavelength long is constant, *merely
interchanging between energy in the electric field of the voltages
and energy in the magnetic field of the currents*." Again, proof
that standing wave energy doesn't flow. It just stands there
being exchanged between the E-fields and the H-fields.
That is from page 40 of "Fields and Waves in Communications
Electronics", by Ramo, Whinnery, and Van Duzer.

Now I did make a mistake in what I said earlier and I apologize for
that. I said the energy in the E-field and H-field exchanges at a
"point" on the line. Obviously, since a current maximum occurs at
a voltage zero, that can't be true so I mis-spoke. Since the voltage
maximum is 1/4 wavelength away from the current maximum, as Ramo &
Whinnery say, one has to consider 1/4WL of line, and not a point as
I said.

Consider a 1/4WL section of line with a voltage maximum at Z and
a current maximum at Z+(1/4WL). The current at Z is zero and the
voltage at Z+(1/4WL) is zero. The net energy in that 1/4WL of line
is constant. No net energy is flowing into or out of that 1/4WL

of line. At some point the E-field energy is strongest toward
the Z end and 1/4 cycle later, it is strongest toward the Z+(1/4WL)
end. Since there is no net energy flow into or out of the line,
there is no net current flow into or out of the line.

> The current oscillation factor (wt) is now decoupled from "z", unlike
> the traveling wave case. The "wave" is stationary. The current itself,
> however, behaves exactly the same as in the case of the traveling waves.

Sorry, you are wrong there, Gene. On that same page, Hecht says, "The
standing wave does not move through space: it is clearly not of the
form f(x +/- vt). For your equations that statement would be: The
standing wave current does not move through the wire: it is clearly
not of the form f(z +/- wt). When you separate the 'z' function from
the 'wt' function, the wave doesn't move anymore. It, well, it just
stands there, like a good little standing wave.

> Of course there are important differences in radiation patterns for
> traveling waves and standing waves. The magnitude of the current is

And stationary as Hecht says. Your own equation indicates that it
is stationary, i.e. not moving.

> I am almost embarrassed to write this, ...

As you should be for not realizing that [Isw = 2Io cos (kz) cos (wt)]
is "clearly not of the form f(z +/- wt)", i.e. of the form of a current
traveling wave that moves. Time to refresh you memory on that subject.

Gene just posted the equation for standing wave current.

Isw = 2Io cos (kz) cos (wt)

This is definitely not in the form of a traveling wave.
Hecht, in "Optics" says the standing wave does not move
through space. Presumably, for the same reason, a
standing wave does not move through a wire.

> Looking
> just at just current, and at only a single point, a traveling current

True but if you know the equation above, then they are distinguishable.

> The only way to understand a standing wave having a phase of zero

Yes, the subject in context is 1/4WL monopoles or 1/2WL dipoles.

>> That's unclear to me. Why can't the E-field and H-field simply be

Yes, I was confused about that. If the question is changed to: "Why
can't the E-field and H-field simply be exchanging energy within each
1/4WL rather than any net charge moving out of that 1/4WL?", it would
make sense.

Thanks John, for the refresher course.

Cecil,

Good grief!!!!

I said several times that the standing wave does not move. I also said the "wave" is not the same thing as the "current". The current is nonzero even though the wave is stationary.

At this point it is obvious that you are just interested in causing a fuss, and not the slightest bit interested in reaching any sort of resolution of this item.

Bye.

Cecil warned me that if I posted, the posting would be nit picked to pieces. I`ve read correct postings describing the incident and reflected waves on a transmission line, and Maxwell`s secret of radiation (displacement current produces a magnetic field same as conduction current). All this may be relevant or not to some extent, but they don`t seem to resolve the current through a coil.

Tom, W8JI wrote:
"You have consistently disagreed with me when I said the time delay through an inductor with tight mutual coupling from turn to turn is somewhat close to light speed over the physical length of the inductor, rather than the time it rakes to wind its way around the copper."

That contradicts established experience.

The property of reactance is to limit current flow. Inductive reactance limits by means of counter-emf which depends upon the rate at which current is changing in the coil. A-C current changes most rapidly at zero time (the axis crossings of the sine waveform). Lenz`s law says the counter-emf must oppose the growth of current in this case. Opposotion of the counter-emf causes the current to reach its maximum 1/4-cycle after the emf applied to the coil reaches its maximum. As almost everyone knows, the current lags by 90-degrees in a pure inductor. Make the turns coupling as tight as you can, the current is still delayed by 90-degrees.

Now, it surely is possible to bypass a perfect inductor with a capacitor to mitigate a delay.

I can`t repeat without retyping text on my screen, so the fact that I don`t retype everything only means I`m lazy.

Right or wrong, W8JI may never lose an argument, but when he is clearly wrong it should be pointed out.

Best regards, Richard Harrison, KB5WZI

No, I haven't, Tom. What you are describing is the voltage delay.
I have never argued with you about the voltage delay through a
coil. It occurs at the speed of light adjusted for VF. In EE101
everybody learns that the voltage leads the current through a
coil. The question is by how much in a 75m bugcatcher coil?

Have you ever seen a graph of the voltage vs current at the
output of a series coil? It shows the current lagging the
voltage by 90 degrees. It takes a series resonant capacitor
to align the current with the voltage again.

> rather
> than the time it takes current to wind its way around through the
> copper.

If you can find a posting of mine like that, I'll give you $100.
If you can't find it, please admit you are fibbing again about
what I have said.

> You didn't like my measurement of a small 100uH choke,

I didn't say I didn't like it. You posted some results and then
described those same results differently as time passed. At the
moment, I have no idea what those results were. Was the -60 to
-70 degree delay a voltage delay or a current delay?

> and said
> a large inductor like a bug catcher coil is different. You predicted
> standing waves in that inductor.

Now we are getting to the truth. A 75m bugcatcher is closer to
being a Tesla coil than it is to being a lumped-inductor. It
satisfies R.W.P. King's advice that if the wire length used
to make the coil exceeds 1/6 wavelength then, "an adequate
representation of the reactance of a coil with a nonuniformly
distributed current is NOT POSSIBLE in terms of a coil with
a uniform current". The 75m bugcatcher uses very close to
1/6 wavelength of wire.

And yes, standing wave antennas have standing waves so a 75m
bugcatcher coil is emersed in a standing wave environment.
Quoting Dr. Corum: "Lumped element representations for coils
REQUIRE that the current is uniformly distributed along the
coil - no wave interference and no standing waves can be
present on lumped elements."

> I have a 100 turn 2 inch diameter air wound inductor of pretty good
> quality. It is 10 inches long.

What is the inductance? What is the Q?

> Please tell all of us the time delay you expect in that inductor on 3.8
> MHz. Please tell all of us what that delay means for your various
> changing theories about waves standing in that coil.

First please describe the circuit used to drive the coil, what other
components are in the loop, and how you are picking off the two currents
at the ends of the coil. Is your Network Analyzer equipped with current
probes? If not, you are wasting your time. We already know the delay for
the voltage will approximate the speed of light adjusted for VF.

Tom seems to be confusing the effects of the E-field with the
effects of the H-field. The E-field propagates at the speed
of light through a coil. The H-field propagates at the
speed of light through a capacitor.

> Make
> the turns coupling as tight as you can, the current is still delayed by

Can the actual current phase delay be estimated knowing the Q
of the coil? I don't recall a formula for that.

Late yesterday afternoon I decided to try the two alligator clips and some wire to run a test to see what would happen. Sounds easy but I made it very hard. To make a long shaggy-dog story short I added the wire and the SWR went out of sight. It acted like a dead short. I then lowered he antenna and cut the wire in half and it was still terrible. I then trashed he alligator clips and wire to and it was still terrible. After two hours of screwing around, I found some dummy (me) had the coax switch on the old Ringo Ranger rather than the W9INN antenna. By this time it was too dark to mess with anything.

Going to start over when the sun comes up but this time I plan to ditch the alligator clips and attach a one foot wire using the connection nuts on the coil/trap or whatever w9inn used to call that thing between the 40 and 80 wires and will have the coax switch on the right antenna this time.

You say you will accept something, you ask for something to be done, and when it is offered you back up and stall, preparing advance excuses why it won't be done correctly and refusing to make a prediction.

You've eaten up hours of my time and the only thing I've learned is you don't want to learn, and you are so unsure of yourself you'll avoid any prediction of how something will work any way you can.

I'm just amazed you have to fall back on name calling, mubo-jumbo, and inuendo when someone offers to help you understand something. I'm all done with this too.

It was a joke, Tom. I am still trying to work out the measurement
details in my mind. It certainly won't do any good to measure
a parameter other than the one we want to measure.

The concept is easy. The measurement it tricky. It won't do
a bit of good to measure the voltage delay and call it the
current delay. I asked you pointed questions about your
coil and measurement setup. Instead of responding with
answers to my questions, you respond with more ad hominem
attacks. One wonders what your motive really is. Did your
measurements support my side of the argument and now you
are ashamed to report those results?

If you refuse to make the measurements, I'll just find
someone else willing to do it or do it myself.

Here comes the junk yard dog guru gang. Tom has refused
to give me the necessary needed information about his
coil and his measurement configuration and you are blaming
me for that? With the information that he has provided
so far, I might as well be trying to guess how much
loose change he has in his pocket.

I'm not stalling, Tom, I'm waiting for you to provide the
information I requested. Why are you avoiding providing
that information? It's pretty simple stuff that anyone
would need to make a prediction.

1. What is the inductance of the coil? What is the
Q of the coil?

2. What kind of current probes are you using with your
Network Analyzer? What are the characteristics of the
driving source signal?

3. What is the schematic configuration of your test setup?
How can I possibly make a prediction without that schematic?

That is certainly a reasonable request. Without that
information, a prediction is impossible, not just for
me but for anyone else.

Now, now, gentlemen, there's no need to re-start the Civil War. Put
away your literary weapons.

The slaves have all been freed and we now have computers.

A 100 turn coil, 10 inches long, 2 inches in diameter, has an
inductance of 102 microhenrys, a Q of aproximately 380 at F = 1.9 MHz,
and the self-resonant frequency is 12.0 MHz.

Its radiation resistance at 1.9 MHz is negligible.

It is near enough to being exactly 100 microhenrys to justify it being
called an Inductance Standard.

Reg.

Assuming the mean RF CURRENT heights are the same and the two antennas
are not violently interacting, you shouldn't see much difference. There
will, of course always be some phasing differences between two different
antennas, even if they are otherwise equal. This cannot be avoided where
signals are being reflected off the ionosphere and the ground.

Roy Lewallen, W7EL wrote:
"The mathematical treatment in King is quite complex. But nowhere does he mention any traveling, reflected, or standing current, power, or energy waves, or that inductance behaves any differently in an antenna than in a lumped circuit.."

Maybe something was overlooked. The above is just more squid ink.

Kraus characterizes inductors as helices. At one extreme they are stretched into straifht wires. At the other they collapse into single loops.

After years of wrangling it is time to admit that the old authors are right.

King and Wing were associates at Harvard.

Alexander H. Wing wrote on page 3 of "Transmission Lines, Antennas, and Wave Guides":
"5. Distributed constants - The Transmission line cannot be analyzed as a simple series circuit, because the current in the wires is not everywhere the same."

J.D. Kraus wrote on page 185 of his 1950 edition of "Antennas":
"Thus, a helix with circumference too small for the axial mode of radiation (circumferennce less than 2/3 wavelength) has a nearly sinusoidal current distribution, caused by alternate reinforcement and cancellation of two oppositely directed traveling waves on the helix of nearly equal amplitude Izero as suggested in Fig. 7-13c. Both traveling waves are of the Tzero transmission mode type."

I expedct no one will throw in the towel, but do expect more squirts of squid ink.

Best regards, Richard Harrison, KB5WZI

Dang! I was looking forward to your test results, and a description
of your test method. I think your 2" diameter coil is a good example
of an inductor that is neither a perfect "lump" nor a pure
transmission line.

I'll bet the measured self-resonant frequency would be lower
if mounted as a base-loading coil on my pickup.

Seems the VF of the coil is 0.041 based on 10" being 1/4WL
at 12 MHz. Assuming that VF holds down to 1.9 MHz we
can calculate the electrical length of the coil on 1.9 MHz
which will be the same as the phase shift through the coil.

So I get about ~14 degrees of phase shift through that coil
at 1.9 MHz assuming the self-resonant frequency really
is 12 MHz at the spot where the coil is mounted.

If the coil were used on 3.8 MHz, the phase shift would
be ~28 degrees.

But my 75m bugcatcher coil shows to be self-resonant at
6.6 MHz while sitting there on my pickup being driven
by an MFJ-259B. It is 6.5" long. When 6.5" is 1/4WL
at 6.6 MHz, the VF = 0.0145, considerably lower than
the coil above and operating much closer to its self-
resonant frequency.

A length of 6.5" coil with a VF of 0.145 on 4 MHz is
~55 degrees of phase shift. And indeed the net current
at the top of the coil drops to about 2/3 of what it
is at the bottom.

That's what my back of the napkin calculations would indicate.
I get ~14 degrees at 1.9 MHz or ~28 degrees at 3.8 MHz based
on 90 degrees at 12 MHz.

But based on what these guys measured before, anyone would be
a fool to predict the results without knowing what the test
setup looks like. In fact, the prediction challenge was a
blatently obvious attempt to lead the unsuspecting down
a primrose path without a roadmap. Do you think W7EL would
ever make a prediction based on the meager amount of
information provided? :-) A few years ago he provided some
information but kept changing parameters daily until I got
tired and withdrew my estimate. But it turned out in the
end that I was pretty close.

Over on qrz.com, Tom was trying to prove Kraus wrong when he said in
"Antennas for All Applications", 3rd edition: "A coil (or trap) can
also act as a 180 degree phase shifter as in the collinear array
of 4 in-phase 1/2WL elements in Fig. 23-21B. Here the elements
present a high impedance to the coil which may be resonated without
an external capacitor due to its distributed capacitance. The coil
may also be thought of as a coiled-up 1/2WL element."

In trying to prove one could not obtain Kraus' 180 degree phase shift
with a coil [because everyone knows the phase shift is always zero],
Tom accidentally let slip the following - quoted from qrz.com:

> W8JI wrote:
>> "By the way, I swept S12 phase with my network analyzer on a
>> 100uH inductor a few hours ago while working on a phasing
>> system. The phase shift through that series inductor was about
>> -60 or -70 degrees on 1 MHz, ... "

Say what? Tom reporting a phase shift through an inductor? Will
miracles never cease?

Thanks for your comments Tom, and you raise some valid points. Jerry Sevick "The Short Vertical Antenna and Ground Radial", pp 25, 26, does state that the procedure is accurate to within 25%, but does not provide any independant verification of these claims. The method was developed by M. C. Waltz at Bell Labs, but, again, nothing was ever published.

It would be interesting to develop a more accurate method. While my measurement of 52 mS/m may not be very realistic it is evident that this region does have a very high soil conductivity. Ground-wave daylight reception of AM broadcast stations, with strong signals, at well over 300 miles is possible.

73,

Frank

I think Reg's estimate of both inductance and first self-resonance (or is that self-anti-resonance?? ;-) are a bit high. Methods I trust all predict about 97uH and self-resonance at very close to 8MHz, for a coil wound with 16AWG to a 2-inch inner diameter. (Inductance would be a bit lower if that's the wire center-to-center diameter.) Winding and measuring one to see which estimate is closer is left as an exercise for the reader, but I wouldn't trust either Reg's or my estimates on this for building an inductance standard (and besides, I'd build such a standard with a lower L/D).

A transmission line model shows 13.5 electrical degrees of line at 1.9MHz, at about 6140 ohms. You should probably look up an article by John Mezak that appeared in "RF Design" some years ago before you to applying that info willy-nilly, but I don't really expect you will. Have fun.

Predictions are little more than an ego trip, unless they are a test
of a specific calculation method used for the prediction. But I was
willing to wait for the test result and an after the fact description
of the test method, to see what understanding might be teased out that
combination of facts. The discussion might also have lead to a better
way to perform such a test.

Baby steps.

>everywhere the same."

Hi Richard,

This FURTHER reveals the foolish pursuits being taken here with this "controversy" of expecting Kirchhoffian results from large systems. When I was a lad, it was first impressed upon us in Sophomore EE that any deviation in measurement from the corollaries of Kirchhoff were signs of:
1. Your mistake;
2. A system too large in terms of wavelength to be analyzed so;
3. Both 1. and 2.

Analog designers, fully expecting a continuum of results spanning from classic to truly exaggerated, can cope with this. For digital designers, this is a clear example of confounding expectations of a binary result.

See program SOLNOID3 which calculates inductance of 1-turn loops, via multi-turn solenoids, to straight wires. With many other parameters of interest such as temperature rise for a given applied voltage, as in tank circuits and antenna loading coils.

So far as the author is aware there are no bugs in it. It's been around and much used for a few years.

Still might. But I suspect the test results are already available
and just being withheld because someone doesn't like the results.
I'm a skeptical, suspicious type. I'm sure Tom wishes he had not
published his "-60 to -70 degree phase shift" results.

Reg, at http://www.ttr.com/TELSIKS2001-MASTER-1.pdf equation (43)
gives the helical wave guide effective characteristic impedance.
Unfortunately, that web site is not responding at the moment (probably
because all the gurus here are accessing it wondering what they did
wrong.) :-) But, when the page becomes available would you take a look
at that equation? It goes something like this:

Zc = 60/Vf[I0(tau*alpha)*K0(tau*alpha)]

Is tau the transmission coefficient and alpha the attenuation constant?
Are I0 and K0 functions? Have you ever seen this equation before?

Also, Fig. 1 is a graph of velocity factor vs the diameter of the helix
divided by the wavelength for 10k, 5k, 2.5k, 1k, 500, 250, 100, and 50
turns per wavelength. It says: "Tightly wound coils are slow wave
structures." My 75m bugcatcher coil appears to fall nicely into the
catagory of a "tightly wound slow wave structure".

The phase shift along a coil, an inductor, considered as a
transmission line, obviously depends on what it is terminated with.
It much depends on frequency.

In the present context, the termination of the coil is the input
impedance of another transmission line consisting of a rod or length
of wire, or a capacitance hat, forming the remainder of the antenna.

To the participants to this discussion, just think about it. The
behaviour of the coil depends on the behaviour of the rest of the
system.

On the other hand, a coil has certain fixed parameters which are
independent of the rest of the system.

It is a good idea to restrict analysis to the resonant frequency of
the system. It assists with simpification and understanding of it.

Tonight, I've switched to Western Austalian dry white.

Reg.

> copper.

I think I have figured out your misunderstanding here, Tom.
I *never* said the current winds its way around through the
copper. That was just another one of your strawmen that
I don't believe and have never believed. I have offered you
$100 if you can find where I ever said that. Would it make
any difference if I offered you $1000?

The effect of a velocity factor of 0.015 may seem to you
to be the same as "current winds its way around through
the copper" but I assure you, if you understood the wave
model of distributed network analysis, you would understand
why that is not the case.

I can fully understand why someone so emotionally
attached to the lumped-circuit model would assume
"current winding its way around through the copper"
but that is simply a misconception of yours.
Distributed networks are not nearly as simple-minded
as your lumped-circuits.

A helical coil structure with a VF of 0.015 *is what it
is*. Waves propagate at 0.015 the speed of light and
that's quite a delay through a relatively physically
short coil. If the coil is 6.5 inches long, as is my
75m bugcatcher coil, it occupies an electrical length
of 6.5"/.015 = 433" = 36 feet. The fact that it consumes
42 feet of wire is just a coincidence. The 6.5" coil
replaces aabout 36' of straight wire. From those facts,
you can calculate the number of degrees or percentage
of a wavelength.

Shirley, you understand that 1/4WL of a transmission
line with a 0.9 velocity factor is longer than 1/4WL
of line with a 0.66 velocity factor. That's why coax
stubs are shorter than 450 ohm ladder-line stubs. (I
feel like I'm doing a EE323 tutorial here).

What is it about a VF of 0.015 that you don't understand?
All it means is that RF through the coil is traveling
at 1/67 the speed of light. If you understand that
RF through RG-8 is traveling at 2/3 the speed of light,
why can't you understand "slow wave coils"?

i.e. the behavior of the coil depends upon the reflected
energy in the system delivered back to the coil by other
elements in the system. That's basically why the lumped-
constant model fails.

> Tonight, I've switched to Western Austalian dry white.

"Austalian"? You've got two choices, Reg. Sober up or
have another. I would have another. :-) But please note,
you have given up a lot of antioxidants from the reds.

Quite right too!

Extremely few SWR meters indicate SWR on the transmission line from transmitter to the antenna where it really might matter but seldom doesn't.

All that is indicated is whether or not the transmitter is loaded with its correct impedance. Admittedly, a useful indication.

The learned discussions on the subject of interpretting SWR meter redings are usually so much baffle-gab.

> Dick AA5VU (red-faced)

The antenna now lives! This morning I added a 14-inch wire to each leg
by attaching it to nut on the 40 meter side of coil/trap thing. The
experiment worked so I know how much I need to cut and solder in on he
40 meter dipole. I may run with the 14-inch wire whips for a week or so
and see what happens. The following is a list of the before and after
SWR readings. The 14" addition did just what the book said it would do.
I now have the 40 meter resonant point pretty close to where I want it
for PSK and RTTY but can still use the phone band as well.

7.600 1.8
7.500 1.4 2.0

7.400 1.1 1.8
7.300 1.1 1.3
7.200 1.4 1.1
7.100 1.7 1.1
7.050 1.8 1.3
7.000 1.8 1.4
6.900 2.0 1.6
6.800 - 2.0

The 50 MHz, 18 MHz, 24 MHz and 3.9 MHz readings did not change and they are all 1.1 or very close.

Bill, W9INN, will be missed. He was a great guy and his antennas were excellent. Too bad nobody picked up the ball from him. My old 40/80 W9INN has been modified to add WARC bands but still works great after 20 years of use and abuse. The traps are still in good shape.

> miles is possible.

There are more accurate methods to calculate ground conductivity, but what's the point? The skin depth in soil is on the order of 10 or 20 feet, depending on the frequency and soil quality. This means that substantial current is flowing down to a few times this depth. Certainly where I live, and I'd bet that in most locations, the conductivity is far from uniform. So in order to know the conductivity of the soil which is carrying current, you'd need to measure it down to several tens of feet.

Once you had that data, what would you do with it? Currently available modeling programs assume homogeneous ground to an infinite depth. So you'd have to choose some single value from among your measurements if your objective is to get better accuracy from a program. But there's no evidence that a homogeneous ground with any single value of conductivity will behave the same as a stratified ground.

So having even an extremely accurate measure of surface conductivity at a particular radio frequency (and it does vary with frequency) still gives you much too little information to build even a crudely accurate model of the actual ground in which the current is flowing.

Absolutely zero reason to place that wire in series with the dipole- in fact
it will not yield the same results if you do so- you will end up having to
redo the length. It will also mechanically weaken the antenna and also
change 80M resonance. There is no current in that short stub-i.e. no effect
on radiation. Let it dangle.

I'm also a victim of Cecil's twisted reality Roy.
I offered to make a measurement if Cecil would even loosely predict
results and tell everyone in advance what they would mean. When he
didn't
respond, I made the measurements anyway.
Time delay measurements of current at each terminal of a "bug-catcher
style" loading coil are now at:
http://www.w8ji.com/inductor_current_time_delay.htm
Cecil is also re-writing what I said on QRZ. If anyone reads back
through
his posts on this list, they will eventually find a post where he
acknowledges a phase measurement I posted on QRZ was in voltage
across the source compared to voltage across a load resistance.
My response was on Mar 9 2006 at 10:03 PM
When I measured CURRENT at each end of the inductor (in that case the
inductor was a 1-1/4" long iron core 100uH choke), current had no
detectable amplitude or phase shift. Voltage from the generator was not

in phase with current because of the inductive reactance, but current
had the same relationship at each end of the choke.
Of course Cecil wrote that off as "measuring standing wave current that

is current that doesn't flow", and then succeeded in driving off
someone who was trying to straighten him out on that. All of that is
also in this thread for anyone to read. The exact text is:

There is no doubt that the readings are different, and significantly in some cases. I will give a calibration of the meter for each band that I do. Lesson learned here is that the meter should be calibrated to do this test, IMO. Yes, it is true that on any given band the readings are going to be relative to each other. But it is inevitable that questions will arise about the relative efficiency of my antennas by band, as both are multi-band antennas.

Part 2 to follow soon.......

> respond, I made the measurements anyway.

Huh? I predicted 14 degrees at 1.9 MHz and 28 degrees at 3.8 MHz
based on Reg's assertion that the coil was self-resonant at 12 MHz.
Once you know the self-resonant frequency, the VF can be calculated.
From there, one can calculate a ballpark delay through the coil.
Your 3 nS measurement seems outside of all possiblity.

This is really simple physics, Tom. If your measurements disagree
with the boundary conditions set by the laws of distributed-
network physics then something is wrong with your measurements.

Let's take a closer look. If the delay through the coil is indeed
3 nS at 4 MHz, the phase shift through the coil at 4 MHz is 4.32
degrees. For a self-resonant phase shift of 90 degrees, the self-
resonant frequency of the coil has to be near (90/4.32)4 MHz =
83 MHz. Now if the self-resonant frequency is really 83 MHz, all
is well, and your measurements agree with distributed network
theory.

But, Tom, don't you think you are insulting our intelligence when
your 100uH coil must have a self-resonant frequency of 83 MHz and
a velocity factor of 0.28 for your measurements to be valid? My
75m bugcatcher coil has a VF of 0.015. Why is your coil 20 times
better than my bugcatcher?

And I have that same coil with 68.5 turns but it is self-resonant
at 57 MHz. How do you explain 2/3 of the number of turns being
self-resonant 25 MHz lower? If you cannot, something is wrong with
your measurements. Don't you care that your 3 nS results are so
outside the bounds of possibility as to be laughable?

Please measure the self-resonant frequency of that coil, Tom.
If it's not 83 MHz, your measurements are bogus. I suggest the
self-resonant frequency is actually lower than the 12 MHz
predicted by Reg.

Incidentally, the IEEE would surely be interested in your ability
to violate the distributed-network laws of physics. Maybe you
can talk them into replacing that body of physics with your pet
lumped-circuit model. Good luck on that one.

3 nS delay through a 100 uH coil???? That would be funny if it
was April First. That's why I requested that you describe your

test setup which you refused to do.

All explainations of the time delay I measured and why it happens are
on my website.

http://www.w8ji.com/inductor_current_time_delay.htm

and

http://www.w8ji.com/mobile_and_loaded_antenna.htm

and associated links.

The self-resonant frequency of the inductor is shown by a large rise in
time delay. Cecil is now trying to rewrite the self-resonant frequency
of the inductor I tested by using his own seriously flawed theories,
but despite the fact it appears to be clearly shown in the network
analyzer data at about 16 MHz.

http://www.w8ji.com/images/Inductor/current-time-delay.jpg

Cecil's normal tactic is to change what other people say. To read a
history of the very same behavior with someone else please read:

http://www.w8ji.com/RRAA_post.htm

John,

If you recall the old W9INN ads in QST you he has a 40/80 dipole. It
was full size 40 meter dipole with what I remember he called a resister
(that was really a coil) and about a 9 foot length of wire past the coil
for the 80 meter antenna. It was fed with coax to a center insulator.
Bill did not believe in baluns.

I modified the antenna by two sets of wires. One for 10 MHz and the
other for 18 MHz. The 18 MHz seems to be resonant for 6 meters and the
whole mess works on 24 MHz as well.

I did not see it on the K2HG web page

Well then, if 10" is 1/4WL at 16 MHz, its velocity factor is 0.054.
10" on 4 MHz with a VF of 0.054 is 0.063WL or 22.6 degrees. Why
didn't you measure 22.6 degrees or 15.7 nS of delay?

You measured 3 nS or 4.32 degrees of delay. Something is obviously
wrong. The VF couldn't change by a factor of 5 to 1 going from 16
MHz to 4 Mhz.

I think I know what happened. You forgot and left the test wire
attached in parallel with the test coil. :-)

In case my previous reply was confusing to some people let's
do it with a piece of transmission line.

We have a piece of transmission line that we measure to be
1/4 wavelength on 16 MHz. That's easily done with an MFJ-
259B. We hand it over to Tom who takes it and measures a
3 nS delay through it at 4 MHz. What's wrong with this
picture?

Certainly, all valid points. I was more interested in actually doing precise measurements, but considered it might improve my model accuracy. I even thought of digging a hole to see how the soil varied. Doubt I would have dug down 20 or 30 ft. Most of the ground here is clay, and then probably bedrock, at this elevation of just over 4,000 ft ASL. Ansoft's HFSS, or CST, could probably handle an accurate, stratified, ground model.

Do a web search for "OWL" (qualifying it with ground conductivity-related terms to cut down the references to the bird and other contexts). I believe it stands for "open wire line", and the last I heard, was the standard way of measuring RF ground conductivity. It involves a buried open wire line, but that's about all I know about it.

There's certainly nothing wrong with learning to measure ground characteristics as an educational process. No matter what seemingly useless learning exercise I undertake, I ultimately learn many other things from it. By all means, go for it.

I'd love to see some results from one of the good field solving programs for stratified grounds, even something contrived, and even a simple vertical with buried or elevated ground system. What I'd like to know is whether there really is a single value you could assign to a single homogeneous ground and get the same results. I suspect not, but have no proof one way or the other.

Message-ID: <dv0r2p$4rv$1@nwrdmz02.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 63361

I am not trolling.

What I want to know is the radiation resistance, referred to the base,
of a short vertical wire above a perfect ground, the current in the
wire being assumed uniformly distributed.

The radiation resistance at the base is in the form of -

C * Square(Length / Lambda)

where Length is the physical length or height of the wire and Lambda
is the free-space wavelength.

What is the value of the constant C ?

Thank you.

Reg.

There's no need to ridicule measurements of soil resistivity just
because at a deeper layer there is a strata of different resistivity.

Any information is far better than complete ignorance.

Roy, you are just displaying your knowledge of geology.

Obviously, in practice it is the resistivity of the top layer which
predominates anyway.

The top layer here Reg is about one to six inches thick of rich pastorial soil. Below that is a layer of red clay with high iron content than can be a few feet or dozens of feet deep, and mixed or below that are various rocks. At places the rock is at the surface.

Measurements of a ground rod at various places on my farm show anything from 50 ohms to 500 ohms for a four foot rod measured against a reference antenna.

What value should I use Reg that would be better than a guess? In the areas where soil is very dry on top but has wet soil below rock, should I use the rock or the soil below it?

The fact is the method using multiple ground rods produces numbers that might have agreed with soil characteristics at the test site, but they produce some very wild numbers other places. I've seen that method produce conductivities of over 40mS/m where ground wave attenuation measurements have shown effective conductivity to be 10-15mS/m.

One fellow on 160 is particularly proud he has 45mS/m soil while his friend 100 miles away has 5mS/m. The only problem is no one can tell any difference in their signals, and there isn't any soil in that area that is over 20mS/m in the AM BC band.

I tghink the best way to estimate conductivity is to measure impedance of a dipole at low heights, and adjust the modeling program until impedances match. That certainly seems more reasonable than using 60 Hz AC on a short ground rod.

C = 160 * pi^2 ~ 1579.

This is exactly 4 times the radiation resistance of a short dipole with linear current distribution (i.e., one without a top hat), since the average current is twice the amount for the same radiated power.

Of course, this assumes an infinitely thin wire. Any real wire will have a higher radiation resistance than this.

Roy Lewallen, W7EL

I used a HP8753C network analyzer with small current transformers
similar to those used in directional couplers.

I calibrated using normal proceedures, and verified calibration by
inserting known transmission lines. For example when I substituted a
very short jumper, time delay was a few picoseconds. When I connected a
10 foot RG-8X jumper, time delay was about 13.5 nS.

For my phase angle measurements I used a dual channel HP vector
voltmeter with a HP generator, and similar current transformers when
measuring current.

I suppose most people would want to use a scope, but it would not be
near the accuracy of a dual channel vector voltmeter or especially a
vector network analyzer.

I have regular test fixture built on blank PC boards, since I do this
stuff every week for work. It does not "fit" a large coil well, so I
had to support the coil on two tall blocks of styrofoam and clip lead
to it.

I do have a large fixture that is a four foot PC board "box" with
various test jacks for connections to probes I use with larger
components, but my bench is to cluttered to fit it right now. In any
event a groundplane several inches away doesn't seem to bother things.
The only thing that moved when I moved the inductor close to the
fixture was the self-resonant frequency came down a few MHz. Time
delays did not change much unless I added an extra foot of clip lead,
then they increased about 1nS.

If it's useful, I guess I could add some more stuff. But probably
nothing extensive until after Dayton.

Since all of my data agrees with data made a few years ago by a
different person using a different method with different equipment, and
since it agrees with reference material I have, I don't see any reason

to treat it like cutting edge results. The physics is pretty solid, and the measurements agree.

Reg, I believe it would be 10*pi^2 = 98.7, half of the
value of a small dipole. Balanis gives a dipole a very
thorough treatment and then says the monopole is half
of those values. His constant in the value of radiation
resistance for a short dipole is 20*pi^2. Kraus rounds
that constant off to 200. That value assumes the short
dipole is not infinitessimal and has a linear standing
wave current distribution. That constant doesn't seem
to need to be a very exact value.

Since the resistance is inversely proportional to the current,
shouldn't you have divided by 4 instead of multiplying by 4?

w8ji@akorn.net wrote:
> When I connected a
> 10 foot RG-8X jumper, time delay was about 13.5 nS.

Let's take a look at the measurement results. That 13.5 nS delay through the coax would make that piece of RG-8X 1/4WL self-resonant at ~18.5 MHz, higher than the specified 16 MHz self-resonant frequency for the coil. So the laws of physics would dictate that the delay through the coil cannot be less than the delay through that piece of coax.

By definition, the physical meaning of that piece of coax being 1/4WL self-resonant at 18.5 MHz is that it takes 1/2 of a cycle in time for the forward wave to make a round trip to the end of the coax and back. 1/2WL of a cycle at 18.5 MHz is 27 nS. So the one-way delay through the coax is 1/2 of 27 or 13.5 nS.

By definition, the physical meaning of that 10" coil being 1/4WL self-resonant at 16 MHz is that it takes 1/2 of a cycle in time for the forward wave to make a round trip to the end of the coil and back. 1/2 of a cycle at 16 MHz is 31 nS. So the one-way delay through that coil is 1/2 of 31 or 16.5 nS.

The 1/4WL self-resonance point *IS* a measure of the delay through the coil just as it is a measure of the delay through a piece of transmission line.

If the coil is indeed 1/4WL self-resonant at 16 MHz, the one-way delay through the coil is *already known* to be 16.5 nS and that is what should have been measured. The fact that the *known value* of the delay through the coil was not measured runs up a red flag and is technical proof that something was amiss with the reported results.

The acronym "OWL", could also mean "Optimal Well Locator", which uses soil conductivity parameters. Dan Richardson's link to a paper by Rudy Severns: http://www.antennasbyn6lf.com/files/ground_parameter_measurements_2.pdf, does refer to the "Open Wire Line" method of measuring ground conductivity, and looks extremely interesting.

I have some minimal experience with HFSS (Also known as "Highly Frustrating Structure Simulator"), and could probably borrow the key to run it at home. Just the same, to model stratified ground you have to know what is underground, so you are back to large back yard excavations. I did notice, during the construction of this house, that the ground appeard to be 100% clay. I could not see any sign of bedrock.

All the grounding info I have seen mentions no sharp bends, or any bends
if you can help it when bonding tower legs, etc to ground rods or ground
rings as it raises the impedance to the ground connection. I can see a
loop in the coax being beneficial as a supplement to a ground system,
but definitely not as the only precaution. It takes a well designed
lightning ground system to take a direct hit without any damage and I
have never seen one in a residential setting. I know several mountain
top repeater sites that take hits all the time with no apparent damage
but the entire site including the building, tower and electrical system
were designed from the start with lightning in mind.

Thanks much. This helps me to visualize your method in a much more
complete way. I think a photo of the test apparatus would make a fine
addition to your web page documenting this result. I am especially

interested on how all this stuff was arrayed in space during the test.

John, would you agree or disagree with me that for
a well-designed coil, the delay through the coil is
fixed by the laws of physics as 1/4WL on the self-
resonant frequency?

If the self-resonant frequency of a well-designed coil
is measured at 16 MHz, then the delay through the coil
is 90 degrees at 16 MHz and therefore equal to 15.625 nS.

Using the self-resonant frequency to determine the
delay is an easy and accurate way to measure that
delay.

If the delay through the coil, measured at 1/4 the
self-resonant frequency, is appreciably different
from the 15.6 nS measured at 16m, then the measurement
contains an error.

Agree/disagree?

You've probably hit the nail right on the head there,
Tom. If your results agree with Roy's then you were
again more than likely measuring standing-wave current
and therefore gained nothing by making those measurements.

How do you explain a well-designed coil exhibiting a
measured delay of 15.6 nS at 16 MHz and a measured
delay of 3 nS at 4 MHz? Don't you realize that is an
impossibility according to the laws of physics? If
the coil is well-designed at 16 MHz, it would also
be well-designed at 4 MHz and exhibit very close
to the same delay at both of those frequencies.
Do you really think the delay changed by 81% between
those two frequencies?

Build yourself an SWR meter calibrated for the Z0
of that coil. Measure the SWR in your coil circuit.
I'll bet it will be nearly infinite. Seems you are
guilty of presupposing the proof again.

Richard,

You didn't read something correctly.

Reg asked for "C" for a small vertical with uniform current over a perfect groundplane.

You are off by nearly a factor of 4 times.

For a monopole with uniform current, C=1580
For a monopole with triangular current C= 395

Radiation resistance is four times greater when the antenna has uniform current.

73 Tom

My bad. I falsely assumed that the length in the
monopole equation was 1/2 the length in the dipole
equation. Another senior moment.

Reg didn't say "uniform current". He said "uniformly distributed
current". A triangular current wave is uniformly distributed,
i.e. it has a linear taper. Seem to me we need to find out
what Reg meant by "uniformly distributed current". I thought
he meant uniformly triangularly distributed. I think Richard
thought the same thing.

Possibly I am doing something really dumb, but have not been able to figure it out. I have been trying to model an inductor in NEC. NEC2 runs ok. If I run NEC 4.1, single precision (NEC4S600), I get a disconnect of 55 micro-meters between segments 300 and 301 -- which is treated as an open circuit (>0.001 of a segment length at 44 micro-meters).

Changing the number of segments, or the number of turns, by one, corrects the problem. Typically the segment end-points are within < 3 micro-meters. I have not identified all conditions when this occurs, but some combinations of segments, and turns, do produce a disconnect. I have not completely investigated NEC 4.1, double precision, but it does run the code below with no disconnect evident.

Tom, W8JI wrote:
"You didn`t read something correctly."

OK, here is the arithmetic.

Radiation Resistance of a Short Electric Dipole:

RR = 80 pi squared (L/lambda)squared

Constant = 80 (8.97) = 790

But a short monopole has 1/2 the resistance of a short dipole.

790 / 2 = 395

All Reg asked for was the constant.

Best regards, Richard Harrison, KB5WZI

I haven't formed a strong opinion either way, yet. I am not an inductor expert, but am learning lots of interesting things, here. I know that filters with sharp resonances (i.e. multiple db ripple chebychev) often have a delay that varies dramatically over rather narrow frequency ranges near cut off.

But I am finding the discussion and test results fascinating. I don't care who has what opinion. I am just interested in what is factual, and sometimes that can be tricky to determine and understand in a more general context. That is why I am interested in the details of the measurement method as much as I am in the result. I am still having a bit of trouble visualizing how the coil was instrumented and terminated to get this result. I am also a beginner when it comes to S parameters.

My reservation with you and few others is your emotional investment in being correct. It makes your opinions less trustworthy. I get the feeling that some of you care more about having had the right answer than what the result tells us about reality.

I have been wrong lots of times, and I got over it (sometimes with difficulty). I accept that I will be wrong about lots more things before I die. The best I can hope for is to realize my mistakes as rapidly and gracefully as possible.

> delay.

For a pure delay process, like a classical transmission line, or acoustic delay line, I agree. I am not so sure for something with more ways energy communicates across it, like an extended inductor.

That is the open question, in my mind.

> If the delay through the coil, measured at 1/4 the
> self-resonant frequency, is appreciably different

> contains an error.
>
> Agree/disagree?

No. Not yet. When the test method has been agreed upon, and exactly what that method measures is understood by all interested parties, there will be no need for such opinions. The results will be the results. Then we can work on our opinions of what the results mean in a more general context (how we extrapolate to other, related, but different cases.

I think Tom did what I did the other night. I hooked the coil
across my IC-756PRO's output, used minimum power, and tried
to supply 4 MHz power to the 4+j1250 ohm coil that I have.
It naturally rejected (reflected) virtually all of that power.
I found, as Tom did, that the standing wave current at both
ends has virtually identical phases but that is already known.
The delay through the coil simply cannot be tested in that
test arrangement. Tom just repeated Roy's experiment of a
few years ago and obtained the same meaningless results.
So did I so I didn't even bother to report them.

> My reservation with you and few others is your emotional

> trustworthy.

Whoa there, I just made a mental blunder about radiation
resistance and readily admitted it. My emotional investment
is in fighting falsehoods, myths, and old wives' tales.
That's all.

The test method for determining the delay through a piece
of transmission line or a coil is the same as it has been
for more than a century. Find the 1/4WL self-resonant
point and calculate the delay. Other methods, resulting
in far different results, are obviously invalid.

In the context of his use, I think the most probably reasonable interpretation of Reg's words is that the current is uniform at all points on the radiator.

Yes, it does also have a constant slope (of zero), so you will ba able to argue a correct interpetation either way, even if the results are different.

It was interesting how many different interpretations were made, and then how many different answers to such a simple questions, even a text book incorrectly quoted (yes, subject to your interpretation of Richard's interpretation of what was in Reg's mind. Reg will no doubt chuckle when he wakes in the morning.

Richard,

Your calculation is OK as far as it goes. However, you overlooked the fact that "L" is different for the dipole and the monopole. The monopole has 1/2 the length of the dipole or 1/4 the length squared.

The coefficient Reg asked for is therefore 4 times the number you quoted.

But the goal of such "fights" should be altering other's opinions.
How's that been working out for you? ;-)

> The test method for determining the delay through a piece
> of transmission line or a coil is the same as it has been
> for more than a century.

Have you got a reference to a Bureau of Standards bulletin on this
method to measure inductive current delay? It doesn't work for
filters made of lumped inductors, capacitors and resistors.
Otherwise, there would not be special designs that sacrifice other
properties, to keep delay almost constant as frequency changes.

Wait a second, an inductor at resonance is a filter made of
inductance, capacitance and resistance (and transmission line
effects). Hmm.

> Find the 1/4WL self-resonant
> point and calculate the delay. Other methods, resulting
> in far different results, are obviously invalid.

"Obvious" must be something in the eye of the beholder.

If a 2 port device (Are there really any perfect 2 port devices that don't have an implied 3rd port?) involves only a single energy transport mechanism from one port to the other, this is a bit closer to obvious. But if the device uses competing, parallel energy transport mechanisms (EM waves, inter turn capacitance, mutual inductance, etc.) it is less clear that the combination of energy transport effects has a constant delay effect on a current wave as frequency changes.

That is *your* logic, and on the basis of it, you have chosen to ignore part of the original question, the explicit statement "the current in the wire being assumed uniformly distributed", without qualifying your one word answer.

> that been working out for you? ;-)

That's not my goal at all, John. My goal is to discuss the technical facts. I really don't care if anyone "alters their opinions" or not. That has been a personality characteristic since my early days. My sister just remarked on that same fact a few days ago. She said, "You have never cared what other people think about you." It wasn't a criticism, just an observation.

We may understand the results of Tom's latest measurement by considering the following:

50 ohm source===1 WL 50 ohm lossless coax===8+j2500 load

Since the transmission line is lossless, this doesn't change anything except for the additional one cycle delay through the line.

What's the system SWR? I get 16000:1. I asked Tom to measure the currents in the absence of a high SWR and he takes his measurements in a 16000:1 SWR environment. How well do you think he honored my request for an SWR of 1:1? Shucks, he only missed it by 1,600,000%. :-)

There is essentially no net energy flow in the above network. Why are we suprised to measure equal standing wave currents on each side of the coil? It wouldn't have surprised me if Tom had measured *zero* phase shift just like the lumped-circuit model predicts. The traveling-wave delay through a coil simply cannot be measured using Tom's methods.

John,

So you are taking a balanced aerial, a dipole, chuck it onto a balun and the feed it with a coax. Nothing wrong with that...

There should not be any "involvement" by the coax in the functionality of that dipole. The grounding of the coax are for shielding purpose only and as such, you ground the coax at one of the terminations, in your case, the transceiver.

Building regs normally demand that the house's mains ground should be connected to a ground rod somewhere, normally at a central point.

Assuming that every level adds 2.5m, you are sitting 5 meter up. Even if you ground your rig with a separate connection to a ground rod, you'll still be electrically 5 meter away from ground (at least).

You will always have RF in your shack <PERIOD>, It's just a question where it is and how you discover it. It's either RF current or RF Voltage. As the

RF voltage is what you normally discovers by having a "hot" key or transceiver, you need to phase shift the ground connection of the coax in time so you have a max current at your rig instead of high voltage.

This is solved by using an artificial ground. Buy or build one, they are dirt simple. MFJ sells one.

The artificial ground is basically a capacitor and an inductor in series with the coax SHIELD(!). Both cap and coil is variable/tunable.
By changing the cap and coil, you can move the RF Voltage and RF current +/- 90 degrees. You just adjust for max RF current at your operating frequency.

This worked fine at the 32nd floor for me...

Cheers

Dan / M0DFI

The word was "resonactor". I have one of his antennas and it works fine.

I have not examined the resonactor in detail, but I believe it is just an inductor which is carefully wound to be self-resonant at the desired frequency, thereby eliminating the need for a separate capacitor to resonate it. A clever idea, since eliminating the separate capacitor easily allows full legal power without the expense of a very high voltage capacitor.

W9INN's trap dipoles are the only ones I know of which advertise full legal power handling, and that's why I purchased one. I've been running full power RTTY on mine for five years with no problems.

Since I purchased mine there may have been other full power trap dipoles come on the market. If anyone knows of one, please reply. I'm always curious about such things.

I am not sure I understand this. As I understand an S parameter tester, both source and load are 50 ohms. Tom says he fed and monitored the signal with a pair of current transformers. I assume that one transformer was fed from the 50 ohm source, and the other fed the 50 ohm load, and S21 is the forward transfer gain parameter that the analyzer can use to calculate a net delay at any frequency. But if I am right about these connections, it leaves open the question of what was on the other side of the current transformers, if the coil was between them. Were those points grounded, terminated, what?

For the answer to that, open your Kraus again, and go to the beginning of the chapter (5) you quoted from. It's explained in the first paragraph. There's even a picture, Fig. 5-1.

If you'll read more in the chapter of Kraus you're quoting, you'll
notice that L is the length of the dipole, not the length of a monopole.
Do the proper substitution and you'll get the correct answer.

As long as someone asserts that there is no phase shift
through a 75m mobile bugcatcher coil, I will continue
pointing out that they are wrong. The phase shift
through a 75m bugcatcher coil is approximately the
same as it is at the bugcatcher coil's self-resonant
frequency. That's simply a law of physics that some
people wish didn't exist but it does in spite of
their wishes.

I don't think he fed the coil with a current transformer.
I think he simply had the coil across the signal generator's
output terminals with current pickup devices at each end
of the coil. The above diagram doesn't change anything
about his configuration but does point out the conceptual
mistake he made which is the identical conceptual mistake
that he and Roy have been making for years. Their model
presupposes their measured results. How could their
results be anything else?

2551. Yagi Antenna Question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-13 01:23:56 UTC
From: chris <cpwendling@yahoo.com>
Message-ID: <1142213036.108163.297200@e56g2000cwe.googlegroups.com>
Source record: 63312

Folks,

I've got a question concerning Yagi antenna's: Why (or how) does the
longer
element "reflect" the radio wave, and the shorter element "direct" the

radio wave.

Also, on many multi-element Yagi designs, the norm seems to be just one
reflector, and many director elements. Does this mean that the
reflector is more "effective" than the directors at modifying the
radiation field?
Why are there no designs with just one director, and multiple
reflectors? Why does the shorter element apparently affect the field
more than the longer elements?

I've seen some interesting 3-D graphics of field strength
renderings for antenna's on the Internet, and some software can produce
some
nice looking 2-D graphics to help visualize the H and E fields. Does
anyone know of a site that let's one vary the element lengths, and
watch the effect on the 3-D graphic of the field strength vectors as
the element
lengths are varied?

Cheers!
Chris AI4MI

One way to beat this is to tune with low power and touch the rig. Every few days increase the power until you have built up a tolerance to the RF tingle.

You could also try this with the household power, starting at 2 or three volts, and increasing it gradually over time until you build up your immunity to electric shock as well.

There is absolutely no reason to have an RF ground unless:

1.) You are end feeding a single wire antenna that is brought into the shack

2.) The two conductor feedline you have brought in, be it coax or open wire, is connected to an antenna that is not properly designed or installed

The safety ground is required. The RF ground is a band-aid for something else being wrong.

Roy, W7EL wrote:
"Do the proper substitutionn and you`ll get the correct answer."

Yes. The warning also appears on page 137:
"In developing the field expressions for the short dipole, which were used in obtaining (5-56), (5-56) is the value of radiation resistance, the restriction was made that lambda is much larger than the length of the dipole L." No problem there, Reg specified a short monopole.

Kraus does a sample calculation for a short dipole. I used Kraus` data and got the same answer when duplicating his calculation.

But Reg was not asking for an answer to a specific problem. Reg was asking for the value of the constant in a formula of the same form. Kraus gives it as 80 pi squared for a dipole.. This is 790.

We know that a monopole has half the resistance of a dipole. Example: 73 ohms and 36.5 ohms. 790 / 2 = 395. That`s not a resistance, it is only the value of a constant which must be multiplied by (L/lambda) squared to give the radiation resistance of a very short monopole.

Best regards, Richard Harrison, KB5WZI

> The coefficient Reg asked for is therefore 4 times the number you quoted.

1.) He could have gotten length correct and assumed current was
triangular. That would reduce radiation resistance by a factor of four.

2.) He could have assumed uniform current and gotten length wrong by a
factor of two, and that would reduce radiation resistance by a factor
of four.

~~~~~~
In a sense, yes it is more effective. Think about it this way: If the reflector does its job, there is no more energy behind it to be reflected any further. Just the opposite with a director. The more it directs the energy, the more there is to be further directed.

When yagis first became popular there were designs published with two or more reflectors. People soon realized the second one added little or nothing and they disappeared.

I suppose if you want really exceptional F/B ratio you could use a second reflector, but most people don't bother. One is enough.

Do you think a loop will stop what three miles of sky could not?
Effective protection is not about stopping a transient. That does not
work and is they myth even used to promote plug-in protectors. A most
trivial earth ground is a massive improvement in protection. That
incoming wire must be earthed - directly or through a protector -
before entering the building. That simplest earthing is many times
more effective than 100 loops. Effective for direct strkes - which
means induced trasnients would be made irrelevant.

The US Forestry Service has documented that most direct strikes to
trees do not leave appreciable indication. Even a standard household
earth ground in conductive soil will provide protection from most
lightning strikes. Then we enhance that earthing for other, more
violent and less frequent direct strikes.

Quality of earthing determines how many direct strikes will be
earthed without damage. Even some earthng to a single point is a
massive improvement in transistor protection. But the loop is about
as useful as bad science fiction. For loop to be effective, then loop
also must seriously degrade radio reception. How many reasons why that
loop is useless? Five?

chris wrote:

>Why (or how) does the
> longer
> element "reflect" the radio wave,

A reflector does not reflect anything. It reradiates.

When a element is self-resonant it reradiates with 180 degree phase
inversion.

Spacing from the driven element causes a phase delay. Lets say that
spacing is 90 degrees.

The phase to the rear direction would be -90+180=+90 degrees. Two
elements like this, when phased and in-line, fire in the direction of
lagging current. So the antenna fires towards the driven element.

>and the shorter element "direct" the
> radio wave.

The shorter element doesn't direct. It reradiates energy. When we
shorten an element and excite it with an external field, the current is
advanced some amount in phase besides having the 180 inversion caused
by reradiating an external field. Let's say we shorten it enough that
the phase advances 120 degrees from the shortening, and we have 45
degree spacing.

Now we have -45 (spacing delay) plus 180 flip (reradiation) = +135
degrees. To that we add another +120 because the element is short and
capacitive. That's +255 degrees. +255 is the same as -105 degrees, and
again since the elements fire in the direction of lagging currents the
driven element's energy is reenforced in the direction of the short
element.

Sorry you asked? Well, that's how it works.

> Also, on many multi-element Yagi designs, the norm seems to be just one
> reflector, and many director elements. Does this mean that the
> reflector is more "effective" than the directors at modifying the
> radiation field?

No.

Once something removes energy form the rear, there is no more energy to
excite and further elements. You can't excite additional reflectors
because there is no energy there to excite them, and so they become
useless hunks of metal without much current.

> Why are there no designs with just one director, and multiple
> reflectors?

Because it doesn't do anything when you put an element in an area where
there is no field to excite it.

Why does the shorter element apparently affect the field
> more than the longer elements?

They don't. They just happen to be where energy has been concentrated,
and as long as they are being excited they can help shape the pattern.

More likely necessary. It is dead simple.

You have a whip with a loading coil somewhere in the circuit under it. The r-f energy is reflected by the open circuit at the tip of the antenna. It must return toward the sender. There is no place else to go.

Anything feeding the antenna is in the path. Volts and amps at any and all points along the way are acted upon by the incident and the peflected waves. Straight wire or coil, the effect is the same as there is a periodic variation in volts and amps due to the combination of the effects of volts and amps from both directions.

Should the current at both terminals of a loading coil happen to be the same, it would likely be a rare coincidence.

Best regards, Richard Harrison, KB5WZI

Tom,

If we assume that there is a well matched antenna: twin line to balun, coax to transceiver. My RF concern was that a long line to ground would serve as an antenna to bring RF into shack. If this is not the case, or if this is easily dealt with, great.

The mains box is on the opposite side of the house...that ground is not conveniently located.

My coax will go thru a lightening arrestor (Polyphase) which will be earth grounded. If I run a low gauge wire from that earth ground to the main box ground, then this is prevents ground loop? What if the distance to the mains box is 60 feet?

John

> I figured you realized that the HP Vector Voltmeter wasnt capable of
> providing the data needed for this discussion.

Here's the procedure for measuring the electrical length of
a base loading coil. That's the same as the delay through
the coil.

1. Mount your base loading coil on your vehicle and remove
the stinger. Note that the current is zero at the top of
the coil with the stinger removed.

2. Use an antenna analyzer, like an MFJ-259B to locate the
self-resonant frequency. It will be the first frequency
going up in frequency for which the reactance is zero and
the resistance is very low. My 75m bugcatcher coil has
a self-resonant frequency of 6.6 Mhz which is an
electrical 90 degrees at 6.6 MHz.

3. Calculate the length of the RF cycle at the self-resonant
frequency. 1/6600000 = 152 nS for 360 degrees at 6.6 MHz.
The coil is an electrical 90 degrees long on its self-resonant
frequency so the delay through the coil is 152/4 = 38 nS.

38 nS is also the approximate delay through the coil when
used as a base loading coil on 4 MHz. One RF cycle on 4 MHz
takes 250 nS so 90 degrees (1/4WL) of that cycle is 62.5 nS.
The coil is providing 38/62.5 = 61% of the antenna on 4 MHz.

Forget the bogus coil delays posted by the "experts". They
are measuring standing wave current which is known not to
change phase on either end of the coil and it doesn't do a
bit of good to measure something that doesn't ever change.

"However, you overlooked the fact that "L" is gifferent for the dipole and monopole."

L is not a constant. L is a variable in another part of the formula. The difference in radiation resistance between a dipole and a monopole is a constant. It equals 2, not 4, not 8, or not 16.

Does it matter that for a vertical that is 1/2 of the length
of the dipole, (L/lamda)^2 is different by a factor of 4?

All one has to do to see radical changes in the currents
at the ends of the coil is move the coil up and down
a 3/4WL radiator. One can find a place where current
at the top of the coil is five times the current at
the bottom of the coil. That's just the way standing
wave current works. Too bad there are so many myths
and old wives' tales being spread about it by alleged
"experts" who have forgotten EE201.

Source record: 63232

The hour is growing late and the urge to tell a story is upon me. Note, that unlike others, I never imbibe alcoholic beverages. This is a true story.

A large, expensive, rotatable LPDA was erected on a tall tower and tested in an informal way with a receiver and short-wave broadcast transmitters as signal sources. Nulls were where they were supposed to be. F/B was roughly what was expected. Front lobe seemed about right.

A month went by and it was time to perform more careful measurements. A 180 swing while listening to a distant carrier suggested that there was more gain off of the back than off of the front! Wise men pondered that this must be a measurement error.

Impedances were very close to expected. The scheme that was used to determine that the antenna needed to be brought back to earth were these:

(Keep in mind that this is a LPDA and not a Yagi.) A 6db pad was put in the line to ensure that the nonexistent impedance changes with no change in frequency would not affect things. An accurate, step attenuator was then added in the line. (Should sound familiar.) Antenna was pointed towards a known very high power broadcast station with a known location such that the expected receiving take-off angle was about 6 degrees. Bandwidth was made very narrow and centered on the carrier. Enough attenuation was added to get the S-meter to average either side of a mark. The attenuation was varied by one db up and down with several minutes at each level. Then the antenna was rotated 180 degrees and the change in attenuation to return to the same indication was noted. Ouch. Repeated several times it became clear that the antenna had reversed direction and (are you listening?) a number for the difference in gain (at the angle involved) and the uncertainty in that number was crafted. Lord K. should have said - and may have said - that all measurements comprise at least two numbers: an estimate expressed as a number and an estimate of the uncertainty in the first number expressed as a number.

The evidence was conclusive that something had happened. A search for causality took place with the assistance of NEC. With a good deal of speculation and noting how the largest elements were constructed, it was speculated that one of the rearmost elements (or a part of one of the rearmost elements) may have become detached electrically. An NEC simulation was produced that fit the data. No, this is not proof, but it did furnish additional support for the need to lower the antenna. More support came from measurements at the high end of the frequency range where no anomalies were noted and where the long elements would not be expected to play much of a role.

At significant cost and effort, the antenna was lowered and it was found that one of the mechanical connections of a sleeve with normal screw had not been tightened in a rear element. The conclusive proof was that the screw had not "cut." Apparently, a month of very sight corrosion had isolated part of an element.

So, be my students and find the lessons in this tale. Make a list.

73 and I am off to bed, perchance to dream of antennas, Mac N8TT

Hi John,

This is required by code. Violate code and insurance can dump your policy faster than a lightning strike.

The whole point of that wire is to prevent ground loops - this one being the mother of all loops. If and when lighting gets snubbed by your arrestor, it will bury that charge into this inferior ground (the non-code unconnected ground that is), lift that ground's potential, and that potential will follow its way into the shack (along the shield) to find your safety ground (which is far better suited for that path) and you might happen to be sitting on the shoulder of that current superhighway.

The resistive earth path between your arrestor ground and service ground is not nearly as attractive as the path from safety ground, through power supply, through chassis, through transmission line shield to the arrestor. It is a rare power supply that breaks that path's DC continuity, and a rarer one that RF isolates it both. Unless you are running solely on battery, no charger, and no accessories connected to the rig - there is a path to ground that lightning will find as an alternative.

60 feet is trivial for safety (the RF in lighting is more LF or MF than HF).

It doesn`t make a ratio different than two to one in the ratio of resistances of the 1/2-wave dipole to the 1/4-wave monopole. We are not comparing a monopole that is the the length of a dipole with the dipole. We are comparing a monopole that is 1//2 the length of a dipole to the dipole when we make the resistance ratio.

The small dipole is working against a perfect ground in Reg`s specification. It would see its reflection in that perfect ground, so its equivalent length is doubled. Kraus` dipole is presumed to be in free space.

Hi Richard

There are sooo many things I dont know anything about. Raster Ammeter is
one of the many things I havent even heard about.
I sure would like to learn how to use a Vector Voltmeter.
Right now, I cant measure impedance (with any confidance of accuracy) when
their VSWR is below about 1.5 to 1 on a 50 ohm line at 137 MHz.

W_Tom wrote:
"Do you think the loop will stop what three miles of sky could not?"

Depends on what kind of loops and how many.

I`ve worked in several broadcast stations that often got struck by lightning. Their towers were the tallest things around. None of these stations got significant damage from lightning. In addition, none of the station equipment powered from the mains or appliances plugged into the mains at the station ever was damaged.

All these stations used tower lighting chokes, one coil for each tower lighting wire including the neutral going up the tower. Three wires, beacon, side lights, and neutral were usually accommodated with tower lighting chokes. Their primary function is to avoid sapping any of the r-f energy from the tower. Another benefit is that the chokes reject lightning too. They are substantial and all turns are wound side by side (trifiler?) around a large ceramic coil form. The wire is large enough to easily handle the load current. I never worked at a station that used Austin tower lighting transformers instead of chokes, but I`ve seen enough of them to suppose they must isolate about as well as chokes do. One station I worked in had an FM antenna atop one if its AM broadcast towers. Its FM coax was coiled at ground level to isolate the AM r-f and it rejected lightning too. So, if you have enough of the right turns the choke does effectively reject lightning. Inductance is proportional to the size of the coil.

The OP asked:
> Anyone have any thoughts on (hopefully not experiences)
> whether putting a loop of, e.g. 1 foot in diameter, on a coax
> run from an outdoor receive-only antenna

One turn of coax is all but not a choke. Then the loop is not located after a better path to earth. It is just a coax loop 1 foot diameter that will somehow stop lightning - without some other path for lightning to seek earth. Somehow it will block lightning and while not impeding radio reception. How many henries stops - not diverts - stops lightning?

Richard Harrison has previously described this choke as part of a system where lightning also has a conductive path to earth. Only with earthing is lightning further discouraged - diverted - by a choke.

Choke can only discourage lightning when lightning has a significantly more conductive path to earth elsewhere. A 1 foot diameter loop of coax does not even begin to accomplish what that choke would, nor is it defined as part of a system that includes earthing. Just some of maybe five reasons why that single coax loop does nothing useful.

A coax loop is really not a choke. A choke by itself does not even stop what three miles of sky could not. But a choke can be part of a system that diverts lightning to some other earthing path. Without earth ground, even a choke would not be very effective. And a one loop of coax does not even perform as a choke would. So many reasons why that coax loops does nothing effective.

Then the numbers. How many henries does a single 1 foot loop of coax cable create? Ballpark - maybe 1 microhenry. How does a microhenry stop or block lightning? Would inductance existing in an uncoiled coax wire actually do more to stop lightning? A significant difference exists between stopping and diverting.

Is all that to mean that you used the formula given by Kraus for a short thin dipole and applied your own rule to halve the coefficient.

In your original response you said "395 It is found on page 137 of Kraus` 1950 edition of "Antennas"."

Is that correct, or did you make the number 395 up according to your own rules and then attribute it to Kraus?

Owen

> if this is easily dealt with, great.

A long line to the ground definitely WILL act like an antenna, but the effect is absolutely unavoidable.

If you look up national electrical codes you'll see external wires or cable grounds entering a dwelling are supposed to be bonded or grounded to the same ground as the power mains and other utilities. This is primarily to ensure if there is any type of ground fault or surge (i.e. lightning) everything in the house rises at the same rate. You don't want ANY surge current flowing through the house wiring, and bonding grounds outside the house greatly reduces currents through the house. This is called a "common point ground", and it REDUCES ground loops.

Second, amateur gear is not normally UL/CSA approved. It sometimes contains high voltage. High voltage inside a metal box can be a problem. If you get a short from a transformer primary to secondary the case can actually rise to the full amount of high voltage. That voltage can appear on antenna cables (as it can if other components inside the box fail), or between that device and other devices. While not all amateur stations have HV devices, most have line operated equipment. It is possible to have 120VAC appear on cabinets and cables in those devices. Because of this, we should always have an independent safety electrical ground. That ground is required by code to be bonded to the service ground.

That leaves us RF. There are only two things required for RF in the shack prevention.

The first is you use an antenna with a two conductor feedline. It can be coax or twinlead. The antenna system can have ANY SWR, but it must ensure the currents on each conductor of the coax or twinlead are perfectly balanced and 180 degrees out of phase.

http://www.w8ji.com/verticals_and_baluns.htm

If the currents are not balanced, some current will flow back to the power lines, telephone lines, and other connections to the station equipment. The cure for this is really fixing the antenna system.

Although a "RF ground" in the station can cover up the problem, the feedline will still radiate and receive signals.

The second is your station must have a common "ground buss" and all equipment in your station should be bonded to that ground buss. The importance of an external low impedance RF ground on that ground buss is actually very minor. The real importance is that ALL equipment in the shack operate at the same RF potential. In second floor locations I actually laid aluminum foil under carpet for my shack RF ground, the large "plate" acting like a groundplane for RF, but I ALWAYS had an external safety ground. That's because I always ran amplifiers and other equipment that was not UL/CSA listed. Sometimes you just do what you have to do to get on the air.

It's best if you work out any RF problems IF they occur. If it was me, I would not worry about RF problems until they showed. Safety is another issue. If you are dead or the house burns down, it is too late to work on problems.

> The mains box is on the opposite side of the house...that ground is not
> conveniently located.

What you do is up to you. I'm only telling you what the NEC tells us we should do and why. It does NOT mean your insurance will be invalid if you don't follow NEC, it only means they can cancel you. State laws require insurance companies honor policies, but if they find out something isn't safe they can cancel you. Otherwise they can only refuse to pay for fraud or an intentional violation of the agreement you signed.

You station is less safe for lightning and for electrical safety if you don't bond the grounds, but I have had many stations over my lifetime that did not follow that guideline. That's what you should do, and you should do it for electrical and lightning safety.

> My coax will go thru a lightening arrestor (Polyphase) which will be

> I don' need no stinkin' VECtor VOLTmeter!

Actually, unlike Tom (who rushes in where angels fear to tread) I cannot figure out how to use the VVM to make a valid measurement of what we are trying to measure. If I cannot figure that out, then the VVM won't do me any good as Tom's setup didn't do him any good and just confused him all over again by tricking him into making his measurement in an SWR = 16000:1 environment. I'm truly surprised his standing-wave current delay measurement wasn't zero.

Guess everyone sees the danger in trying to guess what the results of someone else's measurement will be. Tom should have measured something around 15.6 degrees. The fact he didn't sends up a very large red flag.

Another problem is that the delay through the coil changes drastically between bench isolation and being installed directly above a GMC pickup's ground plane because of the enormous increase in coil capacitance to that ground plane. So the delay through the coil needs to be measured in the physical environment in which it is operated. It is virtually impossible to eliminate reflections from a 75m mobile bugcatcher system so the VVM can't measure what we are trying to measure.

The question is: For a well-designed coil, is the self-resonance method valid for determining the delay through a coil at HF frequencies below the self-resonant frequency? Since that's been an accepted way of doing it for more than a century, I don't see how anyone could object.

Reminds me of what I once told my secretary back in the 70's.
Our lab soldering irons were simple AC devices with standard
AC cords attached. We tied a half-hitch knot in them and used
that loop to hang them on nails on the wall. I was at the
bench one day and my secretary asked me what the knot was for.
I told her that by tightening the knot, I could regulate the
flow of electrons and thus control the temperature of the
soldering iron. Later that night, over drinks at Charlie
Brown's, she and I had a good laugh about that.

Richard, Balanis doesn't say that the 'L' in the monopole
formula is 1/2 the 'L' in the dipole formula. Does Kraus?

Richard,

I guess this must be the week for basic math explanations.

Let's try it with numbers.

The equation shown in Kraus "Antennas", 2nd edition, page 216, for the radiation resistance of a short dipole with constant current is:

Rr = 80 pi^2 (L/lambda)^2

80 pi^2 is about 790, so the equation is rewritten as:

Rr = 790 (L/lambda)^2

In the convention used by Kraus, "L" is the total length of the dipole.

I presume the equivalent discussion is contained in the 1950 edition of "Antennas".

As a test case, let's suppose that L is 8 meters, and lambda is 80 meters. We immediately see that Rr is 7.9 ohms.

OK, now take the monopole over perfect ground that Reg mentioned. The monopole length that corresponds to one half of the test case dipole is 4 meters. The radiation resistance of the monopole is 3.95 ohms.

So, the question becomes determining the correct coefficient for the Rr equation. (L/lambda) is now 0.05, not 0.10.

Therefore,

Rr = 3.95 ohms = X (0.05)^2

I believe you will discover that "X" must be 1580.

This is set up using the definitions for L as stated in Kraus (dipole) and as stated by Reg in his monopole query. Of course you can set up

your own rules, but that would be addressing a different problem.

Gene,

We don't know each other and it may not mean much, but I'd like to thank you for taking the time to explain things so well to people.

This newsgroup, like any public forum, allows anyone to say almost anything without censorship. Because of that two things none of us like to see will happen:

1.) Incorrect information is posted

2.) People get personal in technical conversations.

I left this newsgroup several years ago because it was becoming too personal. One or two people were making it difficult to work through problems or disagreements, and it just wasn't worth the time.

I see now that activity on the group is way down from what it is. Many of the good people no longer post much and far fewer people ask questions.

Hopefully you wil not give up in disgust, and the newsgroup will turn around.

73 Tom

Owen Duffy wrote:
"Is that correct---?"

No, I don`t think so.

Kraus` formula is:
Radiation resistance = 80 pi squared L squared

L is the fraction of a WL made by a tiny dipole.

For the same wavelength, a monopole is only 0.5 the length of a dipole and it has 0.5 the radiation resistance.

If we use its length in the formula abbove, the radiation resistance would calculate as only 1/4 that of a dipole because the constant is the same and L squared is 0.5 squared.

I speculrte from the resistance ratio of a normal dipole to a normal monopole that the answer should be 0.5. So I erred by halving the constant. I should have doubled it to offset the quartered answer an unchanged constant would produces when L = 0.5.

My new and improved answer to what the value of C is:

1580

Best regards, Richard Harrison, KB5WZI

Tom, I am going to ask you some relatively simple technical
questions. If you continue to refuse to answer those
questions, I and the other readers of r.r.a.a will draw
a logical conclusion about your unwillingness or inability
to answer questions, i.e. a non-technical answer or no
answer at all will cause you to lose credibility.

I was wrong about the radiation resistance equation. See
how readily I admitted my mistake? (When was the last time
you admitted a mistake?)

First question is a short one: Please explain why a century
old method of determining the phase shift through a coil by
measuring its self-resonant frequency is not good enough for
you. Do you really expect us to believe that the phase shift
through a well-designed coil can change by 81% from 16 MHz
to 4 MHz?

> Translation of what Cecil actually is saying:
>
> "Whenever multiple measurements by independent sources disagree with me
> the measurements others made must be wrong."

I make mistakes but I seem to be on a solid technical
footing here. A number of readers agree. Maybe you can
convince me and them otherwise if you stop refusing to
answer technical questions about your measurements. Your
100 uH coil is the 8+j2500 ohm load in the following
fixed font example. That's at 3.98 MHz with a Q of 313.

Current probes are at X and Y. How is the following
circuit different from your test setup?

```
+---one wavelength lossless 50 ohm coax-----+
| X
source coil 8+j2500 load
| Y
+-------------------coax braid--------------+
```

The one wavelength of lossless coax doesn't change any values
in the steady-state situation so the current probes at X and
Y read the same value of currents as yours.

The SWR on the coax is about 16000:1. There is virtually
zero net current flowing through the load because of the
extreme mismatch. Virtually all of the current at the coil
is standing-wave current which is known to have unchanging
phase. Roy measured the unchanging phase of standing wave
current and reported close to zero. You measured the
unchanging phase of standing wave current and got close
to zero. It is no wonder you guys get the same value of
current phase delay since you are making exactly the same
error in your measurements spanning a number of years.
I'm surprised that you didn't measure a 0 nS delay.

By gurus as well as everyone else. I asked some technical
question in another posting, Tom. In the past, you simply
ignored my technical questions by trimming them from my
posting and then you objected to my style which is all
that was left.

Let's see if you are still unwilling to answer my technical
questions one of which is:

Why isn't a century old method of determining the phase
shift (delay) through a coil by measuring the self-
resonant frequency good enough for you? How do you
explain an 81% difference between this old accepted
method and your recently measured results?

I disagree unless yoiu are specipically adressing the yagi design
which
is an explanation in terms of vectors.However an element radiates a
field
not a vector. To 'maximise' the redirection of rear field generation
requires
multi "reflectors" or a dish to capture all the rear radiation. Tho a
dish is used
for micro wave frequencies it can be simulated by multi reflectors
aranged in
parabolic form. This method is not as mechanically feasable as the Yagi
but does
illustrate the effectiveness of a "refletor" versus a "director" in
terms of "efficiency"
or "effectivenes" ala, the two element yagi..when viewed as a mesh
cuircuit assembly.
and reradiator ((reflector) longer physical length is not a
necessity.as implicated by the Yagi inline design.

Currently I am looking into the problem of using a common antenna for two VHF transceivers. One operates 30 - 90 MHz and the other from 30 - 512 MHz. They would both be tuned into seperate frequencies and need to share a common broadband, omni directional, vertical monopole.

I think I am getting myself a bit confused (or should I say more confused), do I need to used a diplexer? Would a T piece not suffice as both sets would be tuned to different frequencies and seperation and harmonics would be considered? Would these factors not mean that the input impedance to the set tuned into the different frequency would remain high thus not effect matching?

Other multiple measurements by independent sources agree with
me and disagree with you, Tom. Wonder why you neglected to post
this reference from your own server?

http://lists.contesting.com/archives/html/Towertalk/2003-11/msg00540.html

It is a posting to TowerTalk by Jim Lux, W6RMK. I'll just extract
some excerpts.

"For closewound coils, with length to diameter ratios around 5:1, a
series of fairly careful measurements have been made with the coils
arranged vertically above a ground plane, fed at the base, with a
capacitive load on the other end, and the driving frequency arranged
to be at the resonant frequency of the whole assembly."

Sure sounds like your 100 uH 10"x2" coil installed in a mobile ham
radio antenna environment.

"In most cases, the phase shift in the current at top and bottom [of
the coil] was on the order of 10-20 degrees."

Contrary to the assertions of W8JI. Funny, I predicted 16 degrees for
your coil on 4 MHz based on the self-resonant frequency.

"For inductance the signficant thing is that the magnetic field of
one segment pretty much links to the adjacent segments, and less so
for the rest."

Contrary to the assertions of W8JI.

"At this time, the models are sufficiently well developed that they
predict the actual currents and voltages to substantially better than
one percent ..."

As opposed to W8JI's "accuracy".

"The take home message here, regarding loading coils, is that simple lumped approximations of a loading coil may do just fine for an initial design cut, but do not adequately reflect reality."

"I think it's best to leave it at: Loading coils are not isolated lumped elements and cannot be modeled as such."

To which I add: Since a lumped element model is a subset of the distributed network model, if the lumped element results disagree with the distributed network results, the lumped element results are simply invalid.

Cecil, W5DXP wrote:
"Please explain why a centuries old method of determining phase shift through a coil by measuring its self-resonant frequency is not good enough for you?"

A coil is an RLC circuit. At resonance, L offsets C and all that is left is R. In a resistance, the current is in-phase with the applied voltage.

But, in a physical length of a tuned circuit or in a straight conductor in its place, in a circuit with reflections, you have energy coming from both directions creating an interference pattern, which is repeated every 1/2-wave (180-degrees) in the line Peaks are 1/2-wave apart, considering the velocity factor of the line. To determine the phase shift, count the maxima.

The wavelength of a line is the distance a wave must travel for one complete cycle (360-degrees). If you want the phase shift for a line, take the length of line required for one degree of phase retardation and multiply it by the length of line you have.

Best regards, Richard Harrison, KB5WZI

Hi John,

Well, I for one note that your call for a reference to that one point
(coil self resonance) was met by a "link" to a mailing list on another
point (assembly self resonance).

Be that as it may.

What we do find at that "link" has a rather condemnatory admission:
>>Amateur antennas vary so much in installation and
>>design that a rigorous treatment of one case
That case being a Tesla coil SECONDARY which is notably tight wound
>>would not, in general, be applicable to others.
which quite defines the coils offered here, and are admitted to in the
first words of this sentence.

The thread may now diverge towards Tesla secondary coils and away from
your "well-designed" coil.

The tantalizing part from my perspective is this:

"The measurements were made with carefully designed fiberoptic probes
that were specifically designed to avoid perturbing the magnetic and
electric fields."

I would like to read a full description of this instrumentation.

Art, not to split hairs, or separate bone from marrow, but a single reflector, well dimensioned, and well phased provides more than -20 dB null in the reverse direction. That is less than 1% of the radiated energy goes 'backwards' [99% goes forward]. I'm not claiming the multi-element solution for optimum null, but for us poor hams 1% seems quite good enough.

>But,... ?

Your station can be thought of as a cluster of "black boxes" with
interfaces (eg power, audio in, rx RF in, control, etc) that are
suceptible to damage if large voltages are impressed across those
interfaces.

Hardening a station against lightning usually involves minimising the
voltage impressed across those interfaces in the event of lightning,
and two main approaches are followed (usually together):
1. - reducing the current that enters the station in a strike; and
2. - reducing the voltage drop in conductors within the station that
would cause high voltages across interfaces.

Item 1 is usually done by diverting the bulk of the lightning current
via an alternate path to ground. This means shunting the current
through a low impedance path to ground before it enters the station.
Series impedance on the path to the station may assist in increasing
the portion of the strike current that flows by the alternate shunt
path to ground, but series impedance without the upstream shunt path
is not likely to have much effect. The series impedance you propose is
very small, so its effect will be quite limited.

Item 2. is usually addressed by the design of the earthing system and
equipotential bonding (eg single point earthing).

In summary, a one turn loop in the coax alone is not going to provide
a significant improvement in lightning protection in a station that is
not otherwise hardened against lightning or EMP.

Very interesting, but not enough information to allow me to repeat
their measurements.

I also note that the opening statement:

"For closewound coils, with length to diameter ratios around 5:1, a
series of fairly careful measurements have been made with the coils
arranged vertically above a ground plane, fed at the base, with a
capacitive load on the other end, and the driving frequency arranged
to be at the resonant frequency of the whole assembly."

This definitely specifies only a single frequency for the test. While
it is not the self resonant frequency of the coil alone, it is
definitely a resonant situation, where there will be a considerable
standing wave through the coil. So I don't see how this reference
supports your claim that measuring the delay at resonance tells you
the delay at other frequencies. It also contradicts your claim about
how a standing wave makes it difficult to measure the current delay
through the coil. What have I missed?

If you want to know the velocity factor of a piece of
transmission line, the easiest thing to do is find
its first self-resonant frequency. A little math
will yield the VF which allows prediction of the
phase shift through any reasonable length of
tranmission line.

If you want to know the velocity factor of a coil,

I'll let others delve into the real depths here...

It is possible (some would say likely) that if you dont separate the radios by some antenna line filtering (eg diplexer) one transmitter could damage the others receiver. This will happen even if they are on differing frequencies because it is likely the first amplifying device in line will be made to work across a broad range of frequencies. There is a good chance that you may not notice the damage if the signals you normally listen to are strong, only to find that the blown front device is needed when they get weak.

If you wanted to consider a diplexer you have another big problem in that your operating frequencies overlap and are very wide. Most of these filters tend to work on a fairly narrow band or widely separated wider bands. If you segment the transceivers to specific operating frequencies you can bet that one day you'll want to use the "wrong" transceiver...

You also want to retain a good antenna/transceiver line match. Adding a T piece and more equipment tends to upset that somewhat. The (extra) coax length itself will be a load that best case will reduce the effective power output.

The input impedance of the receiver wont vary as a fucntion of the receiver operating frequency. Unless of course there is some front end filtering which is switched in and out. (Thats unusual nowadays - not having filters keeps the cost down)

I'd suggest that a cheaper path is to use 2 antennas as a diplexer/filter system will be quite expensive. The other way to do it might be via coaxial relays that switched the unused receiver antenna to an attenuator or "open" whilst the other radio is transmitting. This would take some figuring because you want the relays to changeover before the radio starts transmitting.

Hope this is of some help.

Cheers Bob

If the inductor in question does not take much advantage of mutual induction across its length nor has much capacitance across its length (say, a straight conductor, strung with ferrite toroids), then I can see the similarity with a transmission line. But as the inductor approaches a lumped inductance with significant inter winding capacitance and mutual inductance coupling the current across a significant part of its winding length, I see on reason to assume the transmission line method (delay independent of frequency) strictly applies. It might, but it would take more than you saying so to assure me that it is a fact.

In other words, transmission line concepts like uniform inductance per length and uniform capacitance per length get rather muddled in a real inductor.

Bill,

That for the memory jog... the correct term W9INN used was resonactor
and like you said it works FB with or without power. My two resonactors
have been in use since 1978 at three different locations.

I read the question as referring to total radiation and not a specific
angle that you referred to.
With respect to a single reflector it is obviouslythe most significant
addition to a dipole (efficiency
addition if you like)and additional elements added follow a declining
level of addition ofredirected energy (binomial) which I took as his
question. The other questions he raised were follow ups on the yagi
design which fits nicely to the vector style explanation without going
to deep into true antenna radiation thus raising the question of
reflector "length" It really is the same as explaning
"skin depth" without reference toi "volume" or capacitance that does
not refer to "skin depth",.
Most who ask a question may well accept "thats the way it is" but the
gentleman asked the question with respect to reflector length because
of yagi type explanations, which does not "fit"
with all arrays which are actually meshed cuircuits and more difficult
to address.
I have no quarrel with the choice of a two element antenna in the real
world because as Moxon states it is simpler and more rewarding to raise
a two element antenna than to make a three element antenna BUT
it depends on the end parameters that you require which if not stated
lead to perennial radio antenna arguements which plague forums.

> inductor.

Tom W8JI posted a good description and summary of inductor operation a little while ago, but it looks like it could bear repeating, perhaps with a slightly different slant.

In a transmission line, a field at one end of the line requires time to propagate to the other end of the line. As the EM fields propagate, they induce voltages and currents further down the line, which create their own EM fields, and so forth. These propagating fields and the currents and voltages they produce make the whole concept of traveling voltage and current waves useful and meaningful.

But in a tightly wound inductor, a field created by the current in one turn is coupled almost instantly to all the other turns (presuming that the coil is physically very small in terms of wavelength). Consequently, output current appears very quickly following the application of input current. The propagation time is nowhere near the time it would take for the current to work its way along the wire turn by turn.

Once again it's necessary to point out that I'm speaking here of an inductor which has very good coupling between turns and minimal field leakage or radiation, for example a toroid. If you make an air wound inductor and slowly stretch it out until it's nothing more than a straight wire, it'll begin by resembling the toroid -- more or less, depending on how well coupled the turns are and how much its field interacts with the outside world -- then slowly change its characteristics to resemble a straight wire. There's no magic transition point. So by choosing the inductor, you can observe behavior anywhere along this continuum.

Hello:

Am about to start stringing some coax from an outside Receive-Only antenna's Balun up to
my study where the receiver is. (30 MHz on down listening)

The easiest thing for me is to run it alongside an existing (looks like coax, but am not sure) wire
that Comcast has strung for my broadband service to the PC. Actually to their always-on modem which is then
connected to the PC.

Was wondering about coax to coax noise transfer into the receiving antennas coax from being right alongside
this Comcast stuff.

Think there's any reason for concern ?

If so, worth the trouble to find a new route for the receiving antenna's coax ?

Thanks,
Bob

Like many others I don't know everything. In line with reducing my
ignorance could you amplify on how the phenomena is measured with a
"fiber optic probe". What type of transducer is used to convert energy
of an electrical nature to energy of an optical nature with out
"perturbing the magnetic and electric fields".

Yes, a 75m mobile base-loaded antenna is a single frequency
antenna. Why are you surprised? Those guys have figured out
something that I haven't, probably because they have better
tools at their disposal than I do. They seem to have a 1%
accurate model at frequencies other than the self-resonant
frequency. I, OTOH, am only sure of my accuracy at the
self-resonant frequency due to the limited tools at my
disposal.

> So I don't see how this reference
> supports your claim that measuring the delay at resonance tells you the
> delay at other frequencies. It also contradicts your claim about how a
> standing wave makes it difficult to measure the current delay through
> the coil. What have I missed?

You missed the complete point, John. If one cannot eliminate
reflections from the measuring process, then use them to your
advantage in the measurements. Self-resonance means that the
forward wave is in phase with the reflected wave. The first
time that happens is when the wave has made a 180 degree round
trip to the tip of the antenna and back, i.e. it happens first
at self-resonance, when the coil is electrically 90 degrees
long. For a well-designed coil, like a well-designed transmission
line, it doesn't vary by much over HF frequencies. In short,
the self-resonance velocity factor should extend pretty well
to all HF frequencies below that self-resonance point. I need
to think about the frequencies above the self-resonance point,
but that doesn't apply to the present discussion.

I guess I should re-phrase my statement. Standing waves make
it difficult for *ME* and W8JI to measure the current delay
through the coil. I ran essentially the exact experiment that
W8JI ran with identical results. I even used the current pickups
that W8JI kindly furnished to me. The only difference between

W8JI and me is that I recognized the results to be bogus.

>Think there's any reason for concern ?

If the Comcast cable was installed properly, there shouldn't be a
problem. Coax cable with high-quality shielding leaks very little
signal, and the cable companies have to use well-shielded cable in
their plants in order to avoid leakage of channels whose fall into the
airband, amateur, and public-safety allocations.

Also, I don't think that Comcast's plant is likely to carry much, if
any content below 30 MHz.

There's some possibility, I suppose, of some leakage of noise from the
cable modem itself back up along the outside of the Comcast coax. You
might want to consider buying a few snap-on interference-suppression
ferrites, and snap 'em onto the outside of both cables (e.g. where the
Comcast cable leaves the building, where your receiver coax enters the
building, and maybe a few more scattered along one or both coaxes).
This would help block or dissipate any RF currents flowing on the
outsides of the coaxes.

David,

Could it be something as simple as the use of a fiber optic cable as an alternative to a shielded coax cable? I suspect the "without perturbing . . ." part may be innocent overstatement. Wish I had a set of high-frequency probes with fiber optic cables!

Chuck

Hi Dick,

Dale has got it EXACTLY right here! Variable-length stubs from the
inboard screws on the "resonactors" is how Bill (W9INN) INTENDED
his antennas to be tuned! He called this--logically enough--"stub tuning."

The obvious advantages of stub tuning are:
1. It's much easier than changing the length of the primary antenna wire,
and
2. The two (or more) bands can be adjusted INDEPENDENTLY of each
other; i.e., changing the length of the 40m stubs does not affect 80m
tuning; and changing the length of the 80m stubs does not affect 40m
tuning.

This is absolutely the right way to build dipoles in which precise tuning of
resonance is desired.

Now that you've got your 40m resonance set to mid-band, you're pretty
much done on 40m; you can get the full band under 2:1.

But 80m is another story. Because of the "resonactor" loading (which
conveniently reduces overall length), your 2:1 BW is probably 90 to 140 kHz.
By changing the 80m stubs, you can put this wherever you want in the 80m
band; but it's still pretty narrow.

I made a small mod on my W9INN 80/40/17 dipole by putting Rat Shack
banana sockets on the ends of the primary 80m stubs. This enables me to

swap stubs (each with its own banana plug), to move the 80m resonance around in the band. Because my antenna is in an inverted vee configuration with fairly low ends, it's easy for me to change the stub(s).

My normal tuning point is 3950 kHz, where I get 1:1 SWR. To move to 3850 kHz, I plug in ONE stub of appropriate length. (Absolute mechanical symmetry isn't necessary; in fact, asymmetry in the preferred direction can actually lower SWR.) It takes me 90 seconds to go from my second-floor shack out to the antenna, make the change, and come back again.

Naturally, the WX is sometimes such that I don't want to go outside and play with stubs. That's one reason I just replaced my trusty W9INN with a Buckmaster OCF; but the Buckmaster is a subject for another thread.

Like you (unlike W8JI) I don't know everything. :-) I have
hardly any idea how they used a "fiber optic probe" to make
their measurements. I suspect they superposed local RF phasors
and used a fiber optic system to report the results. That's
what I would do.

I have invited Jim, W6RMK, to join the discussion. Maybe
he can answer your questions.

"All the other turns"? Here's what Jim Lux, W6RMK, had to say
about that:

"For inductance the signficant thing is that the magnetic field
of one segment pretty much links to the adjacent segments, and
less so for the rest."

Less to the 3rd, less than that to the 4th, even less than that
to the 5th. What do you think it might be by the time it gets
to the 80th turn on Tom's coil? Seems that we can assume that
the linkage between coil #1 and coil #80 is negligible.

> Once again it's necessary to point out that I'm speaking here of an

> leakage or radiation, ...

So was W6RMK.

> There's no magic transition point.

Indeed there isn't. I repeat, in case your didn't understand -
indeed there isn't. So you can discard your magic lumped-
circuit model for a system containing reflections.

Simple...

Get a two port circulator. That'll solve your problem (but at a price. Try E-Bay). At your low frequencies, try build one yourself.

Regarding the impedance, that is not that problematic. You can basically transform any impedance to your taste. You will incur signal loss tho'.

Also, as you unfortunately are looking at the lower end of the RF spectra, all these parts will be bulky but it's still possible.

Cheers

Possible, but a bit tricky to set up, since you'll need quite a few db of isolation between the ports for this to work even reasonably. 60db would be enough for separations in the range of 10mhz or more, but below that, you're starting to need 75 or 80db in order to hear something on the other receiver.

If it's only necessary to use one radio at a time, then maybe 25 or 30db would do it OK, since all you really need to do then is prevent receiver damage. But if it's desired to use both radios simultaneously, then the more isolation, the better.

I hope NOT!! I run 1 KW in coax that runs right alongside my COMCAST installation. My internet connection [COMCAST W-B modem] is 75 feet from the station and I run 75 feet of COAX right next to it [within 1 inch].

No problems in the computer or TVs [three].

Tom, W8JI wrote:
"A reflector does not reflect anything. It radiates."

Call a parasitic element anything you like, but the convention has already set in.

Kraus tells the Yagi-Uda story on page 246 of his 3rd edition of "Antennas". He writes:
"He (Uda) found the highest gain with the reflector about lambda/2 in length (they must be near resonance to get excited properly) and spaced about lambda/4 from the driven element, while the best director lengths were about 10% less than lambda/3."

Uda`s reports were published between March 1926 and July 1929. There has been much fine tuning since then.

On page 245, Kraus writes:
"When the parasitic element is inductive (longer than its resonant length) it acts as a reflector. When it is capacitive (shorter than its resonant length) it acts as a director."

Shortwave broadcast station I worked in about a 1/2 century ago used parasitic arrays of horizontal antennas. They were called "curtains". We did the adjustments of reflector phasings near the earth. The reflectors had feedlines like the driven elements, but were connected to short-circuit stubs instead of a transmitter. The shorting bar location was adjusted for the proper phase lag behind the driven element. It`s easier than trimming the reflector.

We hung sampling loops from the driven element and reflector and fed them to an RCA WM-30-A phase monitor exactly as were used in medium wave broadcast stations for maintenance of directional arrays.

You could have used such a phase monitor to check the phase difference introduced by a mobile loading coil. It is an oscilloscope fitted with a precision phase shifter which identifies which of the 4 quadrants the phase difference falls in and the number of degrees.

The parasitic reflector performs the function of reversing the direction of much of the energy traveling toward it. Someone in this thread said it can be 99% effective. I also recall reading somewhere that if you are constructing a 2-element parasitic array, you`ll get more gain from a director than from a reflector. Our broadcast plant was behind our reflectors so it made sense to protect it in spite of perhaps a slight gain penalty.

Best regards, Richaed Harrison, KB5WZI

The current measurements Roy and I independently made using different equipment and antennas on resonant antennas aren't valid, according to Cecil.

The measurements I made on multiple inductors on the test bench in a non-resonant system terminated in a load resistor aren't valid either, according to Cecil.

What do all these measurements have in common?

The phasors were on stun. ;-)

2636. RTV Silicone And Coax Outer Jacket: Safe ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-13 23:59:34 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <Bf2dnXDoeID5movZnZ2dneKdnZydnZ2d@comcast.com>
Source record: 63197

Hello:

Is it safe to use the typical GE RTV silicones against a Polyethylene (PE) coax outer jacket ?

I know the RTV's use some type of acid (acetic ?) to cure the stuff, and I was wondering if
anyone might have any first hand experience if there is any kind of interaction with a coax outer jacket ?

Thanks,
Bob

A yagi works exactly as I described. It is nothing more than a
parasitically excited end-fire phased array. The beam forming mechanism
in a Yagi is nothing even remotely similar to the beam forming in a
wide area array like a dish or a broadside-collinear array.

Tho a

> or "effectivenes" ala, the two element yagi..when viewed as a mesh
> cuircuit assembly.

Not true.

The gain in a dish comes from the wide area of surface that is excited
in phase. The dish surface looks like multiple dipoles all excited in
exactly the same phase. Gain is not high because a reflector is "more
effective", it is high because a wide area of radiation (multiple
wavelengths wide) can be used to focus the forward beam.

This is why USIA Curtains for SW broadcast have substantial gain, as do
bedspring arrays at VHF and UHF. Dishes are much more closely related
to broadside-endfire arrays than any other antenna, and work on very
different principles than a Yagi.

The Yagi relates closely to an end-fire array, and that includes the
reflector.

This is why you do not see any yagis with multiple in line reflectors
and very few with trigional or sheet relectors, and why you do not see
dishes with directors. The workings
are entirely different.

(snip)

I don't think so. Your claim is that one can use a resonant condition
to find the current delay at that frequency, and then, assume that
that delay holds for all other, lower frequencies. I am skeptical
that this is the case for any device that is not inherently a constant
delay device. I think you are assuming your conclusion. You may be
right, but you can't prove it by assuming it. You have to demonstrate
it, (or find a reference where someone else does that) to be
persuasive. I am rooting for you, because this would be a handy
technique, but I am still skeptical that it is generally applicable.

According to the labels I've read, much of the consumer-grade RTV does
in fact release acetic acid as it cures. Not good stuff to use around
electronics or other metals.

The noncorrosive, "moisture cure" or "neutral cure" RTVs are a better
choice for use around electronics. The ones marketed as "electronics-
grade" are the surest bet in this regard, and usually need to be
mail-ordered. A possible compromise would be the consumer-grade RTVs
which are specifically advertised as being noncorrosive for use on
metals - the labels on these say that they release methanol and
ammonia during cure.

2642. Re: Yagi Antenna Question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-14 01:32:25 UTC
From: art <aunwin@insightbb.com>
Message-ID: <1142299945.392458.73220@i40g2000cwc.googlegroups.com>
Source record: 63203

Tom
I read as far as the word "tho a"
and you made my day, you confirmed what I suspected that all
antennas are based around yagis and not about antennas in general which
is exactly the point I made earlier.But your explanation tho correct
for a yagi is not all encompasing.
If you contend that your explanation over rules the mesh or field
aproach i.e a reflector must always be a longer radiator completely
avoids the essence of the first question i.e long versus shorter
reflectors. When aproached from a meshed
circuit point of view it can be seen that coupling of radiators behind
the dipole generator can easily produce an element(s) of a shorter
length.since as you stated a reflrctor does not reflect
but creates a reactive field in conjuction with other elements in
the immediate field to satisfy Newton's law
The rest of your reply I consider irrelavent to what was previously
stated and thus diversionary to the subject at hand.
If you read the initial post carefully you will note that his question
revolved around the length of reflector (s) which in essence calls for
a different aproach to the traditional format
based around a yagi .It is for this reason that such questions are
raised by those who apply deeper thought to the subject,
ask this question over and over again and cannot be explaned
unless coupling of individual fields are brought into play instead of
introducing personal rules similar to front to back ratios which
is a point ratio of energy efficiency rather than a overall array
energy efficiency. and so on.

I wouldn't think anything but extremely good grounding
at the antenna will do much.

Long ago, when I lived on the west central coast of
Florida (lightning alley), I had a 6-meter repeater on
a tall building. The transmit and receive antennas were
at diagonal corners of the building (no duplexer).
We got a direct hit on BOTH antennas. The damage
was something to see. Antennas had no damage except
some scorch marks, but the coax was another matter.
There would be 2-3' of coax, then 2-3' of nothing but
scorched roofing. This repeated across the entire 150' or
so length of the coax! A whole bunch of RG-8 simply
vaporized.

Hopefully the poster mentioning the optical probe will explain a bit more. But I recall seeing optically coupled instrumentation used in an EMI screen room to couple signals in and out. To my knowledge, though, the probes themselves were conventional, and fiber optics were used only to replace connecting wires.

Roy and John;

The fiber optic leads are used in the experiment mentioned in the story linked by the URL that was recently mentioned in this thread. I think the whole thing is hilarious and was especially struck by the use of glass fiber to measure an electrical/magnet phenominum with no indication how the measurement is made. Sort of in line with someone's line of thinking in this thread.

> So, be my students and find the lessons in this tale. Make a list.

Lesson #1 - Put the thing together correctly. Check the connections.
Check it again.

Lesson #2 -some people needed to hone their troubleshooting skills. If
the antenna had performed well during the initial tests, using an
analysis program is probably the last thing to do. The time to do
analysis was long past.

I don't know much about antennas, (which is why I'm here) but I do know
troubleshooting. All the numbers that popped up on the tests and the
simulations were just blind alleys for y'all to go down and get beat up
in. Something changed in that month. Is it likely that the laws of
physics changed? Much more likely something in the installation was at
fault. The antenna should have been lowered when the second tests were
so different than the first ones. Of course following rule #1 would have
obviated the need for that!

That's an interesting point. Suppose you have a two-element driven array with the elements spaced a quarter wave apart and fed 90 degrees out of phase. This produces a cardioid pattern, which has a deep null. Is the element toward the direction of the null "reflecting" and the other one "directing"? If so, what are they "reflecting" and "directing"?

Each element intercepts considerable energy from the other and reradiates it, if that makes a difference.

Here's another one: Build a 4 square array, assuming the ground is perfect. (The EZNEC example file 4Square.EZ or demo equivalent d_4Square.EZ can be used to illustrate this.) If you disconnect the feedline to the rear array element and short circuit the feedpoint (by deleting Source 1 in the EZNEC model), you'll still have a moderately good directional pattern with about 15 dB front-back ratio. The rear element is now a parasitic element, which we like to call a "reflector". You've said it "reflects by radiating". Now connect the rear element feedline as in the original antenna. The front/back ratio improves. But the feedpoint resistance of the rear element is negative. This isn't particularly unusual in driven arrays -- it means that the element in question is absorbing power from the other elements and sending down the feedline toward the source. The element is still radiating, because current is flowing on it. But it's absorbing more power from the surrounding region than it's giving back in the form of a field. (Again, the excess is being sent back along the feedline to be used by the other elements.) So, is that element now "reflecting"? If so, is it "reflecting by radiating"?

2654. Re: Phase shift circuits

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-14 03:44:26 UTC
From: Harry Gross <harry144@optonline.net>
Message-ID: <u_qRf.1227$MG6.644@fe10.lga>
Source record: 63215

Hi all,

I'm toying with the idea of an 'electronically rotatable' dipole setup.

Consider: a dipole oriented N/S
another dipole oriented E/W
They cross each other at the mid-point of each, forming a big plus
sign, like so:

```
|
|
----+----
|
|
```

If you feed the N/S dipole, you get an E/W radiation pattern.
Similarly, if you feed the E/W dipole, you get a N/S radiation patter.

If you feed the N/S and E/W dipoles simultaneously, you get a NW/SE radiation pattern (for example), and if you flip the feed of either one of them 180 degrees, then you get a NE/SW radiation pattern.

So far, so good. Now for the fun part. If you feed one of the dipoles with a signal that is only 90 degrees out of phase (or 270 degrees), you can get radiation patterns that take of in the NNW/SSE or WNW/ESE directions, and if you feed the other dipole 90 or 270 degrees out of phase, you get NNE/SSW and ENE/WSW directions.

What I am looking for is a circuit that can perform the necessary phase delays, without having to use miles of coax coiled up in the shack. Ideally, the circuit would be able to perform the phase shift on all (or at least several) ham bands, so that it could feed into a pair of fan-dipoles for operation on multiple bands.

Anyone have any suggestions on just how to accomplish this? In the extreme case, you could have a continuously adjustable system, that would permit you to point the 'virtual dipole' in any direction at all, which might be useful when attempting to null out an interfering station off to the side of the desired signal. However, in practice, I suspect that the eight positions mentioned above would be sufficient to do the same thing (albeit with the possibility of somewhat more signal loss due to fixed aiming directions).

I seem to recall seeing a quote in the ARRL Handbook (or the ARRL Antenna Book) from Roy Lewallen, indicating that there is no simple way to do this. Am I mis-remembering (or mis-interpreting) what I read?

I know that the military does this sort of thing with radar systems, and has for some time. However, their budget is quite a bit bigger than mine, so perhaps their solution isn't 'simple':-)

Any thoughts on this, anyone?

Harry Gross

> to find the current delay at that frequency, and then, assume that that
> delay holds for all other, lower frequencies.

At other *HF* frequencies and within reason, John, within reason.
A two to one range wouldn't surprise me. Tom's five to one range
from 16 MHz to 4 MHz is surprising. If the frequency kept going
to 1 MHz, would the delay go below 3 nS? If Tom measured the delay
at the self-resonant frequency of 16 MHz, would he measure 16 nS?
If one plots the delay from 1 MHz to 16 MHz would there be any
nonlinear points on the curve as implied by Tom's measurements?

> I am skeptical that this
> is the case for any device that is not inherently a constant delay
> device.

I didn't mean to imply that it was an absolutely constant
delay device. If it is well designed and if the environment
is held constant, it should exhibit approximately the same
delay over HF below its self-resonant frequency. Tom's
measurements implied a 5 to 1 range shift in delay from a
4 to 1 range shift in frequency. Delays changing faster than
the frequency certainly don't make sense to me. What would
be the cause?

From 16 Mhz to 4 Mhz:
Does L vary much with frequency? Why?
Does C vary much with frequency? Why?
Does R vary much with frequency? Why?
Does G vary much with frequency? Why?
These are the parameters in the "phase constant" equation.

Let's take a look at my measured data where I changed the
stinger by 2 feet from zero to 12 feet. The 75m bugcatcher
coil is mounted on a mobile antenna mount on my GMC pickup.
For clearence purposes, it has a one foot bottom section.

The stinger goes from 0' to 12': 0, 2, 4, 6, 8, 10, 12
The resonant frequency goes from: 6.7, 5.1, 4.3, 3.8, 3.5, 3.2, 3.0 MHz
I just don't see any nonlinear changes such as Tom reported.

Trying to bridge the gap between engineering and English, I would
suggest this analogy:

A mirror reflects light energy fed to it, while a light bulb takes
electricity and turns it into light.

Either a mirror or a light bulb can be used to send light in a desired
direction, but only one is "reflecting" that energy in the usual sense
of the word. Likewise, only the mirror is "re-radiating" energy, much
like a yagi's reflector does.

The analogy is not perfect but that's what the words mean to me.

Addressed to nobody in particular.

From basic transmission line theory, the velocity of propagation along a coil is estimated by -

V = 1 / Sqrt(L * C) metres per second,

where L and C are henrys and farads per metre respectively. The formula for L and C can be found in your Bibles from coil dimensions, numbers of turns, etc.

The velocity factor = V / c and Zo = Sqr(L / C).

Attenuation (loss) = R / 2 / Zo nepers, where R is wire resistance plus radiation resistance.

From which other interesting facts can be deduced.

Reg.

> ... I see no reason to assume the transmission line method
> (delay independent of frequency) strictly applies. It might, but it
> would take more than you saying so to assure me that it is a fact.

Assume the environment of the coil is fixed like the variable
stinger measurement I reported earlier. Besides the frequency
term, the phase constant depends upon L, C, R, and G as does
the Z0 equation. Why would the L, C, R, and G change appreciably
over a relatively narrow frequency range as in my bugcatcher coil
measurements going from 6.7 MHz to 3.0 MHz?

And I didn't mean to imply that the delay is "independent" of
frequency, just that it is not nearly as frequency dependent
as Tom's measurements would suggest. If Tom made his measurements
from 1 MHz to 16 MHz, what do you think the curve would look like?

Freq 1 2 4 8 16 MHz
Delay ___ ___ 3 ___ 16 nS

That looks non-linear to me. How about you?

Bob,
I have been using GE 1200 on coax and connectors since the early
seventies and have never had a problem with it affecting good silver
plated or cheap connectors or the varying grades of coax I have used.
If you want to be fussy cover the connector with electrical tape and
then cover with silicone. This makes it easier to remove but is not
necessary for protecting the connector or the coax. I would not use
it inside of a radio or other electronic equipment but outside of that
it will not hurt and will keep the connection free of moisture, BTW,
if you do wrap it with tape first be sure to coat the coax past the
tape to ensure a good waterproof seal.

2661. Powerline trap

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-14 04:13:06 UTC
From: Owen Duffy <owen@no.where>
Message-ID: <t3gc12hgeam243af8vg7s5tell59lmkts1@4ax.com>
Source record: 63221

You probably haven't thought of powerlines as an antenna, the BPL industry pretends they aren't, but they are.

A recent news item is about a new patent for a "Filter for segmenting powerlines for communications" (US 7,005,943). It is described:

"There is provided a method for blocking a portion of energy of a signal in a power line. The method includes equipping a high frequency magnetic core with a coil, connecting a capacitor across terminals of the coil to create a resonant circuit that resonates at a frequency of the signal, and placing the magnetic core around the power line, at a location where the blocking is desired."

Hmmm, a trap! Without getting bogged down in the details of the coil and the current / phase relationships, is this likely to be effective? A parallel resonant trap in an antenna doesn't eliminate current beyond the trap at the frequency of trap resonance. Will it make the region of the powerline between the injector and the trap a better radiatior for the same injector power?

Thoughts?

Owen

Apparently not. That was a private email. Publishing it in public without my permission is unethical but seems you and Tom will seemingly stop at nothing to keep promoting your myths.

You have, over and over, rejected the distributed network model even though you know it is a superset of the lumped-circuit model. Would you agree with me that after all this time, you cannot possibly plead ignorance?

There exist transducers that will convert RF to light on one end of
a fiber optics cable and back to RF at the other end. It's no big
deal and keeps the transfer of information from being affected by
EM fields.

So Reg, for a fixed installation, why would L and C change
much with frequency, like from 16 nS at 16 MHz to 3 nS at
4 MHz? If we took it down to 1 MHz, would the delay go
below 3 nS?

So you believe my personal feelings about you are relevant
to a technical discussion???? Exactly which technical
parameters are affected by my feelings about you?

Every time this subject comes up, more and more people
realize that the r.r.a.a gurus are not omniscient.

Here's a smattering of the email I've received over
the past week. Unlike you, I won't mention any names.

"I hope ... that [X and Y] will acknowledge the validity
of your approach." [X and Y are posters to r.r.a.a]

"You are moving pretty fast, but nothing that you are saying
sounds like there are any glaring errors."

"Distributed constants not lumped constants prevail."

"I, too, am skeptical of that 3 ns delay."

" ...your Corum reference certainly ends the debate."

"I want to let you know your dedication to principle and rational
analysis ... are inspiring to many of us."

"The unwillingness of the "gurus" to answer specific technical
questions is pretty disappointing."

Roy, are you listening to that last comment?

From: K7ITM <k7itm@msn.com>
Message-ID: <1142312610.017971.218740@v46g2000cwv.googlegroups.com>
Source record: 63130

Could you describe more fully the phase-shifted case? When I simulate it, I get a nearly non-directional pattern... that's with two dipoles, separated vertically by a tiny amount, with a current source at the center of each. That's as I'd expect, since that configuration has been used for a very long time as an omnidirectional horizontally polarized antenna for things like FM broadcast reception.

But why not just vary the relative amplitudes in the two dipoles? Then you can rotate the pattern fairly easily. (The pattern when both elements are contributing won't be quite as sharp as a simple dipole, but the null could be useful on receiving.) You can use a variometer to change the relative amplitudes. A variometer consists of two coils in mechanical quadrature, with the center point of the two coincident. Then at the center, there's a rotating coil. So you feed power to the rotating coil (or feed your receiver from it), and connect the two fixed coils to the antennas.

It's a big help that the two dipoles in that orientation don't couple to each other (at least in an "ideal" installation).

By the way, if you Google "variometer," you'll probably find references to just one fixed coil with a rotatable one inside it. That's not the only kind...maybe the one I described above has a name; I tried "quadrature variometer" with no real luck.

Cheers,
Tom

Well, one thing for darn sure - those 2 radios sharing the antenna should be able to hear each other really really good - (till they destroy each other's front end.)
Given the parameters (sharing some of the same frequencies) - the only way to share the antenna is by unplugging the coax from one radio and pluggin it into the other. - Or using a good coax switch - (which could conceivably be a relay)
But I may be wrong.

That's right - a bolt of lightning comes streaking across several miles of
dry air, finds the antenna with no problem, then upon seeing the loop, ducks
back into the ground.
But at least the loop will make the rain drip outside. It not useless.

You're correct that a trap doesn't stop current -- or energy -- at the trap. The lines on both sides couple with each other, allowing substantial current to flow on the side away from the source. All the trap does is guarantee a current null at some point. A quarter wave away, a current maximum will occur. In fact, a trap can increase current coupled into a wire if it breaks a formerly non-resonant wire into pieces of which one or more are near resonance.

Source record: 63135

The advice to avoid acetic-acid smelling RTV because of corrosion is passed along from person to person like an urban legend, but like an urban legend it's just about impossible to find anyone who's actually seen any corrosion result from its use. (A number of queries I've made over the years has produced just one, using a very early version of RTV.)

I've used the acetic-acid smelling stuff for decades on a variety of metals including tinned and untinned wire, aluminum, nickel, and copper circuit boards, and never seen a hint of corrosion. But formulations vary widely, and my experience certainly isn't exhaustive. I'm not entirely convinced, though, that among the many formulations there aren't others, which don't have that smell, which might be corrosive to some materials.

People who worry about this should buy an industrial product and stay with it, since there's a much better chance the formulation won't change in the future without notice.

The two dipoles don't couple to each other, so you have a lot of options
for feed systems. Transmission delay lines are one. Another is lumped
circuit networks -- an L network can be designed to effect a range of
phase shifts.

I think you'll find, though, that you'll hardly be able to tell when you
rotate the array in any increment smaller than 90 degrees, and unless a
signal is pretty close to a null, even that rotation won't make a
striking difference. It's a problem that's easily modeled, so I'd start
by seeing just what I might gain from it before going to the trouble.

Thanks Roy,

Given that BPL band plans often have a link bandwidth of several MHz,
one wonders also about the effectiveness of a trap in compromising
depth of notch vs bandwidth. Perhaps the magic bullet is really a band
stop filter, I didn't look the patent up.

But no matter, it seems it serves more to organise the location of
standing waves rather than eliminate current past the trap.

Of course, we are all scratching our head about the technical elegance
or even feasibility of BPL (or lack of it, more to the point).

Such probes are routinely used for RFI, RF hazards and screened-room measurements, where connecting wires would disturb the fields or act as pathways for RF leakage.

They do have a disadvantage that might be relevant to this discussion: because the probe head has to be self-powered, and has to include some kind of encoder and optical transmitter as well as the normal current transformer, the battery and extra area of PC board will increase the probe's self-capacitance.

A different kind of fibre-optic probe is used in basic research on RF hazards, to measure very localized and very small temperature changes in simulated human heads and bodies. These microprobes are purely optical, and are sensing some temperature-dependent optical property of liquid crystals(?) at the probe tip.

Well, it's actually not that tricky!

If you use a dual port circulator, you will not have any problems.

The only problem is to find a broadband dual port circulator.

I've read that most of the lightning starts at the ground first and
reaches into the sky to find the other end.

On second thoughts, since L and C are functions of a coil's physical
dimensions it must be something else which is changing with frequency.

There are two advantages to a fiber optic coupled probe. One advantage of fiber optic coupling from probes to indicator is the coupling leads from sensor to indicating instrument do not have a good direct path to earth or equipment like conventional probes. Ian points that out above.

I actually built a form of optical coupled probe for one of the measurements Cecil
rejected.

http://www.w8ji.com/building_a_current_meter.htm

In this case the information, current, is conveyed by light through air directly to my eye. I moved the indicator to the probe. For the purposes of this discussion, however, the real advantage might be different. Since it is unlikely anyone has a fiber-optic coupled probe (the fiber optical cable simply replaces the wire between

the sensor and the indicator or sensor information processing system) it is unlikely anyone can make a measurement proving Cecil's theory wrong.

This is what seems most logical to me:

The pattern has been after Cecil gets measurement results and finds they
disagree with his theory, he rejects the measurements. Measurements using a magnetically coupled indicator are rejected because they measure current that isn't moving (despite the fact it has to be a flowing current to produce a magnetic field).

The most logical thing any person can do when they repeatedly reject any disagreeing data supplied by multiple people using different equipment and methods is to come up with a measurement device no one has or can build.

The original debate was K3BU and W9UCW made a statement current is high

only in the first few turns of a loading inductor, and thus loading inductor Q did not matter for efficiency of an antenna. This effect was attributed to the coil replacing antenna length, and the sine shaped curve of antenna current must thus exist in the loading coil.

I proposed antenna losses were swamped out by ground losses in a vehicle, and because of very high ground losses the effects of coil resistance were diluted. I pointed out in a very small (in terms of wavelength) two-terminal device the current entering one terminal must always equal current leaving the other terminal, and that the current must be not be shifted in phase.

Yuri K3BU argued the coil replaced a certain number of degrees electrical height, and I
disagreed. I said a 20-degree long antenna with a loading coil did NOT have 70 degrees of antenna wound up in the coil.

I measured the inductor and found as quite logically anyone would expect that current ratio depended on the ratio of stray C from the coil itself (providing the third terminal) to load C at the open end of the coil.
Most people experienced in systems like this from an engineering standpoint agreed with me.

Somewhere about that time Cecil brought reflected waves into the discussion.
After a series of "what happens if" measurements were made. When measurements were made both Cecil and Yuri announced the measurements proved their
points. The person making measurements corrected those misstatements and pointed out the measurements didn't support Yuri and Cecil's claims.

See:

http://www.w8ji.com/agreeing_measurements.htm

The only recourse for Cecil and Yuri was to dismiss those measurements and
my measurements and demand new measurements.

When more new measurements again disagreed with the concept of huge current
or phase delay of current that was tied to degrees of antenna the coil replaces,
the only course was to again reject the disagreeing measurements.

So here we are today, two or three years later, still trying to find a measurement method that will agree with what Cecil and Yuri proposed, that a loading coil behaves as a coiled up antenna or transmission line

rather than behaving more like a lumped component in a small heavily loaded mobile antenna.

Since dozens of hours of measurements acceptable to most people were rejected, the only end to this debate would be to require a measurement with
instrumentation no one has. This way Cecil can say no one can prove him

wrong, and that allows him to continue to demand others agree with him.

In my opinion, the real advantage of optically coupled probes in this thread is no one is likely to have them. Since no one has them and that is all Cecil will accept, Cecil can not be proven wrong by a method Cecil will accept.

I guess I'll have to break down, buy a copy of EZ-NEC and play with it:-)

By the way, are you suggesting that 90 degree rotation is all I'd need, simply because the dipole radiation pattern is so wide, broadside to the radiator? If that turns out to be true, then the problem becomes vastly easier to deal with, and could even be done mechanically by simply switching around the feed line to one dipole (easier to do with ladder line - the preferred feed line to a dipole - than coax, of course) although that might not be the BEST way to do it.

Harry,

If you feed 90- degree delay, the result is a basically omni pattern.
It has some ripples, but not much.

I think all you would ever be able to use is one antenna, the other
antenna, or both antennas together either in or out of phase.

I can't see any reason to do anything like rotate phase or control
ratio, since the effects would be so small.

HI Roy,

I have been using a different product for over a decade that works
great - liquid vinyl tape. It does a heck of a job for sealing
water-tight connections and, like RTV, doesn'g get hard and crack.
You can buy it a most hardware stores.

Its easy to use and, like was suggest earlier in this thread, I first
wrap the connection with regular vinyl tape (a single layer) before
appling the liquid compond - its makes for much easier removal when
needed.

w8ji@akorn.net wrote:

Before I comment on your posting below, I think you can prove
to yourself that your measurements are flawed. You measured
3 nS delay through your coil at 4 MHz. Now perform the same
measurement at the self-resonant frequency. The delay through
the coil is known to be 15.6 nS at the self-resonant frequency.
If your delay measurement isn't 15.6 nS, then there is something
wrong with your methods. Better yet, measure the delay at 1,
2, 4, 8, &16 MHz and report the results.

> ... it is unlikely anyone can prove Cecil wrong.

That's because in order to prove me wrong, you have to prove
yourself right. You simply haven't done that because you refuse
to engage me at a technical level. You have ignored my technical
questions and refused to discuss the technical details. Many
readers have noticed that, wonder why, and have commented on
it in emails to me.

> This all seems logical to me, because Cecil has asked for measurements.
> The pattern has been after he gets measurement results and finds they
> disagree with his theory, he has to blame the difference on something.

Tom, your measurements agree perfectly with my theory. You are
measuring standing wave current. That standing wave current
magnitude is pictured in every good book on antennas. Kraus
also shows the phase which, for a thin wire dipole, is fixed
at zero from tip to tip on the antenna. It is understandable
why you measured zero standing wave current phase shift through
the coil. THE STANDING WAVE CURRENT PHASE SHIFT IS ZERO WHETHER
THE COIL IS IN THE CIRCUIT OR NOT!

Since the phase of the standing wave current is fixed and
unchanging whether the coil is in the circuit or not, why do
you think measuring that unchanging phase around a coil proves
anything?

> I proposed antenna losses were swamped out by ground losses in a
> vehicle, and because of very high ground losses the effects of coil

The following reports a 10-20 degree phase shift through most coils.

http://lists.contesting.com/archives/html/Towertalk/2003-11/msg00540.html

> Most people experienced in systems like this from an engineering
> standpoint agreed with me. Somewhere about that time Cecil brought
> reflected waves into the discussion.

Those "most people" don't understand forward and reflected waves on a standing-wave antenna. You have proven by your postings here that you do not understand forward and reflected waves on a standing-wave antenna like a 75m bugcatcher mobile antenna. Worse yet, you refuse to discuss the antenna at a technical level and have simply sandbagged your misconceptions.

I remember when you were using the lumped inductance feature of EZNEC to try to prove your point, certainly an invalid proof. When we started this thread, it was obvious that you didn't know the standing wave current phase is fixed near zero degrees so measuring it is futile.

> After a series of "what happens if" Cecil wanted measurements. When
> they were made, he and Yuri announced the measurements proved their
> points.

Yes, they did prove that the current at the ends of the coil were NOT equal. You said they were. I said they were not. Out of all of your and Roy's measured results, the current was equal in only the case of the small toroidal coil and that's because it was located at a standing wave current maximum (loop).

> When the person making the measurements corrected those
> misstatements and pointed out the measurements didn't support their
> claims, the only logical course was to discredit the measurements and
> ask for new ones.

You sure have selective memory, Tom. I fully accepted your standing-wave current measurements. But standing-wave current measurements cannot be used to measure the traveling-wave delay through a coil. That should be obvious to everyone by now. The delay through the coil causes a phase shift in the forward wave and the reflected wave, not in the standing wave. THE PHASE OF THE STANDING WAVE CURRENT IS KNOWN NOT TO CHANGE AND THAT'S EXACTLY WHAT YOU MEASURED, VIRTUALLY NO SHIFT.

Kraus agrees. Figure 14-2 of "Antennas For All Applications", 3rd edition shows a graph of the phase of the standing wave current. That phase is zero tip-to-tip for a thin-wire 1/2WL dipole.

> When new measurements again disagreed with the concept of huge current
> or phase delay of current that was tied to degrees the coil replaces,

> the only course was to reject those measurements.

THOSE MEASUREMENTS WERE NOT REJECTED! They were accepted as perfectly valid measurements of standing wave current. Those characteristics are pictured in Kraus and your measurements agree perfectly with them. Your argument is a strawman. The fact is that a standing wave measurement CANNOT yield the current delay through the coil any more than it can yield the current delay through a wire. YOU CANNOT MEASURE THE DELAY THROUGH THE COIL USING CURRENT KNOWN NOT TO CHANGE PHASE!

> So here we are today, two or three years later, still trying to find a
> measurement that will agree with what Cecil and Yuri proposed or for
> another person of reasonable engineering experience to agree with the
> notion the coil behaves as a coiled up antenna or transmission line
> rather than behaving more like a lumped component in a small heavily
> loaded mobile antenna.

This is not about you or me or Yuri. It is about getting down to the truth. Yet you rave on and on about personalities. Why don't you discuss technical issues instead of personalities?

There is a phase shift in the forward current through the loading coil. There is a phase shift in the reflected current through the loading coil. Those phasors are rotating in opposite directions so the net phase is fixed. You can measure standing wave current phase in thousands of experiments from now to kingdom come and you will not be measuring the phase shift of the forward and reflected current through the coil. Your measurements, so far, are meaningless. You have NEVER measured the delay through the coil.

I guess I'm going to have to draw you some pictures and post them on my web page.

> Since dozens of hours of measurements acceptable to most people were
> rejected, the only solution would be to require a measurement with
> instrumentation no one has.

I fully accept your standing wave current measurements, Tom, but standing wave current measurements will not yield the information that we are after. We need to know the phase shift in the forward and reflected currents through the coil. Standing wave measurements simply will not yield that information. Self-resonance measurements will yield that information. The delay through a coil that is self-resonant on 16 MHz is 15.6 nS.

Just curious, Reg, are you familiar with phasors used to
represent traveling waves where the phasor has a rotation
about the origin proportional to the frequency? Are you
familiar with the phasor addition of two of those waves
traveling in opposite directions forming standing waves?

Or maybe nothing is changing appreciably over relatively
small frequency excursions. Maybe the measurements are
not measuring what someone thinks they are measuring.

The only experiment so far that has actually measured the
delay through a coil is the self-resonant frequency
measurement.

Tom's and Roy's results are perfectly consistent with
the measurement of standing wave current whose phase
is known to be constant and unchanging. That measurement
yields no new information.

I was visiting a local SGC dealer years ago as he was troubleshooting a brand new antenna tuner that was not working. When he opened the plastic case, that special RTV acidic smell almost knocked us over and all the tinned circuit board traces and exposed wiring were corroded and black. SGC claimed they used the wrong type of RTV on a batch of tuners that was not for electronics use.

Not true, Tom, please stop saying such. I fully accept and embrace
your measurements of standing wave current, already known to possess
unchanging phase. Kraus has a graph of exactly that. Your measurements
are PERFECTLY consistent with standing wave current measurements. What
they are not consistent with is traveling wave current which undergoes
a phase shift through the coil as yet unmeasured by you.

Why don't you stop talking about you and me and discuss the technical
issues?

> The most logical thing any person can do when they repeatedly reject

That's not true either. A lot of hams can measusre the self-resonant
frequency of a coil and know the coil exhibits a 90 degree phase
shift at that self-resonant frequency.

> The only recourse for Cecil and Yuri was to dismiss those measurements
> and my measurements and demand new measurements.

This is ancient history, Tom. I have learned a lot since then and
would appreciate you dragging yourself back into the present so
we can discuss technical issues, rather than personalities. For
the present discussion, what happened in the past simply doesn't
matter as I don't believe the same thing I believed three years
ago. Things are not as simple as I first thought.

> So here we are today, two or three years later, still trying to find a
> measurement method that will agree with what Cecil and Yuri proposed,
> that a loading coil behaves as a coiled up antenna or transmission line

Three years ago, one could not use constant phase standing wave
current to measure the delay through a coil. Today, one cannot
use constant phase standing wave current to measure the delay
through a coil. Nothing has changed. Standing wave current is
what it is. Making the same measurements three years apart
doesn't prove anything new.

> Since no one has them and
> that is all Cecil will accept, Cecil can not be proven wrong by a
> method Cecil will accept.

Again, a false statement. I am not asking for fiber optic measurements. All I am asking is that you measure the delay through your coil using exactly the methods as before, and report the results for 1 MHz, 2 MHz, 4 MHz, 8 MHz, and 16 MHz, the self-resonant frequency for which the delay is already known. When you do that, you will probably know what is wrong with your conclusions. There's nothing wrong with your experiment if you really want to measure the phase shift of a standing wave current known to have unchanging phase. Your measurements are perfectly consistent with the laws of physics.

Please stop re-hashing the past. This is three years later. I've learned a lot in those 3 years and have changed my mind about a lot of things. Please just discuss the technical details and leave the personalities out of it.

If the only way you and Roy can dispatch me is at a personal ad hominem level, doesn't that speak volumes about not being able to dispatch me at a technical level? Are you guys engineers or just attack dogs?

For instance, compare the ad hominem stuff in your above posting to the technical content.

Tom wrote, "I can't see any reason to do anything like rotate phase or control
ratio, since the effects would be so small."

One reason to rotate the pattern (however one does it) is to use the nulls to kill an interfering signal when receiving. Other than that, there's certainly not much reason. Even with one-or-the-other of a pair of crossed dipoles, at 45 degrees azimuth from max on a perfect dipole pattern you're only down about 4dB from max, and if you add in the feed-both-in-phase (or 180 shift), the patterns cross at about half a dB down from max. Note though that the pattern for both fed in phase is a bit broader than that of a single dipole.

Harry: you can simulate all this with the free demo version of EZNEC, I'm sure.

Cheers,
Tom

Cecil, W5DXP wrote:
"Kraus agrees."

Pity the fool that argues with Terman or Kraus!
In Kraus` Figure 14-2 of the 3rd edition of "Antennas", the 1/2-wave is resonant and shows no phase shift from end to end. In Figure 14-4, phase is shown to make an abrupt phase transition at a point 1/2-wave back from the open circuit at the tip of the antenna. This is predictable from the behavior of an open-circuited transmission line as shown by Terman in Fig. 4-7 in his 1955 edition.

Kraus` Figure 23-21 shows how a self-resonant coil can replace a short-circuited 1/4-wave stub in a phase-reversing trap. If you don`t have the 3rd edition of "Antennas", get it.

Cecil wrote: "I am not asking for fiber optic measurements."

Very likely they aren`t necessary. I`ve measured currents along antennas draging a sampling loop along them with a rope. A transit determined the position and its telescope made the r-f ammeter in the loop readable.

Surely a loop and its ammeter can be small enough not to upset the measurements if you use enough power and have a low enough frequency. As Richard Clark might say: "We don`t need no stinkin` fiber optics."

Best regards, Richard Harrison, KB5WZI

We are not talking about L, C, R, or any other inherent property changing with frequency. We are talking about the delay of a current wave in a single direction (anybody have a pair of directional coupler current probes?) through a complex component that has several different mechanisms that contribute to the total current passing through it. It is the vector sum (superposition) of those current components that is in question. Over a narrow frequency range, it is conceivable to me, that the phase (delay) of that sum might shift, dramatically, though any component of that sum might change its magnitude only slightly (no faster than in proportion to the frequency), and the phase of that component might change not at all.

> And I didn't mean to imply that the delay is "independent" of

> That looks non-linear to me. How about you?

Definitely nonlinear, just like impedance is very nonlinear as the frequency passes through any resonance. This is why I am suspicious of a measurement made at resonance, being extrapolated to non resonant conditions.

2696. Modeling question

Newsgroup: rec.radio.amateur.antenna

From: Bob Bob <bob3bob3@cox.net>
Message-ID: <u0cje3-6h5.ln1@p400bob.personal.cox.net>
Source record: 63157

On a learning curve here. I'll admit I am after a fast answer or two.

Using 4nec2 to model what will likely be a 2m antenna used at the home QTH. Its an extended double zepp. ie two 5/8's in phase with a hairpin like centre section, the whole thing made of 1/2" copper and fed at 200 ohms with a 4:1 balun or 100 ohm Q section. I have also included the mast but havent really adjusted for best gain. There will be a quad on the other side that isnt modeled yet.

Looking good so far but;

- Is the diameter of the source wire an issue?

- How do I allow for the use of copper pipe 90 degree elbows used in construction. If I model them as (say) a extra single wire at 45 degrees to mimic the radious I run into segment len/diameter limits.

Any thoughts or feedback welcome. Nec file attached inline. (Apologies for the line breaks) I have yet to go through convergence testing and playing with numbers of segments in the shorter sections.

Cheers Bob W5/VK2YQA

> conditions.

Self-resonance is simply where the round trip delay through
the coil puts the forward and reflected voltages and the forward
and reflected currents either at zero degrees or 180 degrees.

That's what happens at an open-ended 1/4WL stub.

That's also what happens at the feedpoint of a resonant
standing wave antenna like a 75m mobile bugcatcher antenna.
Resonant mobile antennas are "self-resonant antenna systems".

I am not familiar with the velocity factor of coils.

> The velocity factor of a transmission line is based on those
> quantities and can be calculated.

Not quite. The velocity factor in transmission lines is based on
ratios:
capacitance per length, and inductance per length.

Where do you get the equivalent length numbers when dealing with semi
lumped inductors?

Most likely because they closed the cases before the silicone had cured,
not realising they were trapping the acetic acid vapour inside. The same
can happen in balun boxes and the like.

It would be interesting to know if there have been *any* cases that
didn't also involve some kind of closed situation, or possibly a layer
that was too thick to let the vapour diffuse out.

The two most humorous parts of this entire thing:

1.) RF current can stand still, yet cause current in a transformer secondary.

2.) We have to use a "directional current coupler" to sort current flowing one way from current floing the other, because of standing wave current.

This entire thing has become almost laughable. It looks like the thread has regressed to the point where people no longer understand directional couplers or current transformers.

Anyone who knows how a directional coupler works is rolling around on the floor laughing at the suggestion of sorting "forward current" from "reflected current".

It appears this thread has reached the lowest level, where impossible to build instrumentation is now demanded as the only acceptable proof.

What a trip!

Glad to see you posting again, Art.

Kraus produced an organization chart of antennas on page 56 of the 3rd edition of "Antennas". In the Kraus plan, the "Yagi-Uda" is among the "End Fires".

The topic is: "Yagi Antenna Question".

Roy responded with:
"Suppose you have a two-element driven array with the elements spaced a quarter wave apart and 90 degrees our of phase."

This driven antenna produces a nice null to the rear as a Yagi can, but the Yagi is a parasitic array, not a driven array.

Steve wrote:
"I wouldn`t think anything but extremely good grounding at the antenna will do much."

That helps.

Company I retired from had radios all over the world. Most base stations used Andrew 1/4-wave stainless steel folded monopoles. These were securely grounded to the tower. The tower had a separate ground rod connected outside the base to each leg of the tower by heavy strap or cable. These radios suffered no lightning damage, despite repeated hits.

Kraus has this to say in kis 3rd edition of "Antennas" on pages 719 and 720:
"---a short-circuited lambda/4 section of coaxial line is connected in parallel with the antenna terminals. This widens the impedance bandwidth and also places the stub antenna at dc ground potential. This is desirable to protect the transmission line from lightning surges."

Whenever we could not use a folded antenna with a single-frequency radio, we connected the shorted stub directly across the antenna and grounded the coax at the tower top. It works.

Might well be. A classic method of blocking single-frequency
interference current from flowing down a feedline is to stick a
parallel-resonant trap next to it. The commonest variety I've seen
described is a wire loop with tuning capacitor. I have no reason to
believe that a core-based version would not work.

>A parallel resonant trap in an antenna doesn't eliminate current

Please provide a technical response to the following.

Hecht, in "Optics" says of standing waves of light in space:
"Its profile *DOES NOT MOVE* through space; it is clearly not
of the form f(x+vt). At any point x = x', the amplitude is a
constant equal to 2Eot*sin(kx') and E(x',t) [the electric
field] varies harmonically as cos(wt)." page 289, 4th edition.

The 'z' movement for a standing wave current magnitude
along a wire is completely divorced from the frequency of
the wave. Its profile *DOES NOT MOVE* through the wire.
Same as light standing waves above. It is not of the
form f(z+wt).

Since standing waves of light in space do not move, why is it
surprising that standing waves of RF on a wire do not move
for exactly the same reason since they have identical equations?
The standing wave energy in the H-field of RF standing waves
will certainly cause current in a transformer secondary just
as the standing wave light electric field will activate a
light detector.

> 2.) We have to use a "directional current coupler" to sort current
> flowing one way from current flowing the other, because of standing wave
> current.

There really may be humor in that statement which I never made.
I've never heard of a "directional current-only coupler". If
anyone knows of one, it sure would solve the measurement problem.

> Anyone who knows how a directional coupler works is rolling around on
> the floor laughing at the suggestion of sorting "forward current" from
> "reflected current".

And I'm one of them. I've never said there existed such a device,
just that if it did exist, it would solve the measurement problem.
As it is, we haven't solved the measurement problem. The only means
I've seen of actually measuring the phase shift through a coil is
using the self-resonance method. Measuring the phase shift of
standing waves won't work because STANDING WAVES HAVE NO PHASE
SHIFT WHETHER THERE'S A COIL IN THE CIRCUIT OR NOT!

> It appears this thread has reached the lowest level, where impossible
> to build instrumentation is now demanded as the only acceptable proof.

It was a wish, not a demand. But we can indeed separate out the
forward wave from the reflected wave in a transmission line by
using a directional coupler calibrated for the Z0 of the line.
We can then carry those concepts over to a standing wave antenna,
according to Balanis.

So consider this experiment.

coil
source---50 ohm coax---X-////-Y---50 ohm coax---Load

We have directional couplers installed at 'X' and 'Y' and
we can in theory look at the phases of the forward and
reflected currents on each side of the coil. Will the
forward and reflected currents through the coil show
a phase shift or not? Seems we should start at a pretty
low frequency (low reactance) and work our way up. I
think the phase shift pattern would be clear.

Note that a cap to ground to the left of 'X' and a cap
to ground to the right of 'Y' would result in a pi-net
tuner. Wonder if there's any phase shift through the
coil in a pi-net tuner? Is a pi-net tuner a "phasing
network"?

How could the coil cause an arc on the Smith Chart
without changing the phase of the wave through the coil?

What's the formula, Cecil? Also, what is the dominant mode
of a single wire, loading-coil transmission line: TE, TM,
TEM, or what? If not TEM, how do you calculate the cutoff
frequency? If I terminate one of these things in the
right impedance will it act like an infinite transmission line?
Given your loading coil terminated in a given impedance, what is
the expression for the impedance looking into it? I suppose you also
have something that will tell us how to find your coil's characteristic
impedance; o.k., out with it. All this bluster and threatening rhetoric
aren't advancing the acceptance of your crackpot theory one inch, Cecil.
I don't see anything wrong with at least attempting to characterize a
loading coil as a transmission line as long as the attempt is done
dispassionately with real theory and an acceptance of the possibility
of failure as part of the effort. Desperately thinking up excuses for
an idea you made up in your head, and becoming emotionally distraught
when people don't buy those excuses, is a waste of your time and
everyone else's.

> As it is, we haven't solved the measurement problem.

I've solved the measurement problem. I measured current and voltage
levels and phase of each.

I've measured time delay of current appearing at the coil output
compared to input.

> We have directional couplers installed at 'X' and 'Y' and
> we can in theory look at the phases of the forward and
> reflected currents on each side of the coil. Will the
> forward and reflected currents through the coil show
> a phase shift or not?

With all the respect I can muster, here we go again Cecil.

Current is current. Voltage is voltage.

A traditional directional coupler works by comparing voltage across the
line at any one point to current in the line at that same point. The
current sampling device is summed at the operating frequency with the
voltage sampling device, and the resulting voltage is measured. When
voltage and current are in phase, the detected voltage levels add. When
they are fully out of phase they subtract.

Now we could build a transmission line system of measuring SWR that
would work the very same way (normally done at VHF). Or we could build
a line section that allows us to slide a probe along it and measure
voltage or current nodes and finding maximum and minimum calculate SWR.

In every single device we would be able to build, we would never be
able to sort reflected current from forward because current is current.
There really isn't any such thing as current traveling two directions
at one past one point in a system.

You have taken this argument to an absolute dead end, because you
insist current can flow two directions at the same time at one single
point in a system.

You are demanding a measurement method that uses a device that cannot
be built to measure something that does not exist. That is either

humorous, sad, or frustrating. It sure isn't science.

The velocity factor can also be measured from the self-
resonant frequency at 1/4WL. VF = 0.25(1/f)

> I suppose you also
> have something that will tell us how to find your coil's characteristic
> impedance; o.k., out with it.

http://www.ttr.com/TELSIKS2001-MASTER-1.pdf equation (43)

The characteristic impedance can also be measured at
1/2 the self-resonant frequency at 1/8WL. For a lossless
case, the impedance is j1.0, normalized to the
characteristic impedance so |Z0| = |XL|.
For a Q = 300 coil, that should have some ballpark accuracy.

We don't need extreme accuracy here. We just need enough to
indicate a trend that the velocity factor of a well-designed
coil doesn't increase by a factor of 5 when going from 16
MHz to 4 MHz.

In "Antennas for All Applications", Kraus gives us the phase
of the standing wave current on standing wave antennas like
a 1/2WL dipole and mobile antennas. 3rd edition, Figure 14-2.
It clearly shows that the phase of the standing wave is virtually
constant tip-to-tip for a 1/2WL dipole. It is constant whether
a coil is present or not. There is no reason to keep measuring
that phase shift over and over, ad infinitum. There is virtually
no phase shift unless the dipole is longer than 1/2WL and then
it abruptly shifts phase by 180 degrees.

I agree with Kraus and concede that the current phase shift in
the midst of standing waves is at or near zero. There is no
need to keep providing measurement results and references.

Tom,

Whenever Cecil gets in a total lather I am reminded of John Belushi in Animal House. "Were you there when the Germans bombed Pearl Harbor?"

This entire saga has been greatly extended and quite thoroughly confused by imprecise and flat-out-incorrect terminology. It probably won't get better any time soon.

Currents, waves, and fields are used interchangeably as the mood strikes. Phase shift can refer to almost anything, it seems. Free-space optics are used as an analog to current in a wire. Descriptions that almost certainly have little transferability from one human to another abound, such as "superposed local RF phasors".

Oh well, it's entertaining, at least for a while.

>
> Does this not work?

This sounds like the "resonance breaker" someone mentioned recently. It resembles a gamma match. You put a wire parallel to the tower for a few feet, then connect the top to the tower through a capacitor. The bottom of the wire is connected to the (grounded) bottom of the tower. This alters the effective height, and therefore the resonant frequency, of a tower. It's a technique used in the broadcast industry to reduce undesired coupling which distorts antenna patterns.

I don't think this method will do more or less than a trap. There's nothing which will stop current or energy at some point, as long as there's mutual coupling from the wire on one side to the wire on the other.

I recall an EMI control class I took long ago, where they told how a brute force power line filter was installed to reduce radiation from circuitry inside a device via the power line. Worked fine in the lab but failed in production. The filter was physically placed where there was room near the front of the unit, and they found that the production folks had neatly bundled the filter input and output wires for some distance, providing a good path around the filter. The same sort of thing happens on a wire with a trap, although the coupling is of course not as strong as between the bundled wires.

w8ji@akorn.net wrote:
> I've solved the measurement problem. I measured current and voltage
> levels and phase of each.

There you go again, "I, I, I". This is not about you. This is
about valid measurements. I concede that when one measures
the current phase shift in a standing wave environment, that
the result will be zero or close to zero. But we are not
interested in measuring a constant phase whether the coil
is in the circuit or not. We are interested in measuring the
phase shift through the coil and it is NOT zero.

Reference: Kraus' "Antennas for All Applications", 3rd edition,
Figure 14-2. Kraus clearly shows if you measure the phase shift
between any two points on a 1/2WL dipole, that measured shift
will be close to zero degrees whether a coil is present or not.
There is no need to keep performing those same measurements.
I agree with Kraus.

We know a 1/2WL dipole is 180 degrees long. The fact that the
standing wave current doesn't change phase from end to end
doesn't mean the 1/2WL dipole is zero degrees long. The fact
that the standing wave current doesn't change phase on each
side of a coil doesn't mean the coil is zero degrees long.

> I've measured time delay of current appearing at the coil output
> compared to input.

There you go again, "I, I, I". It doesn't matter who does the
measurement or whether a coil is in the circuit or not. The
standing wave current's phase doesn't change in the antenna's
180 degrees of length. That has nothing to do with anybody's
measurements. That's just a fact of physics. One cannot
use standing wave current to measure the delay through
a coil OR A WIRE in a standing wave environment.

If one takes a known 30 degrees of a 1/2WL dipole and uses
standing wave current to measure the phase shift through
that 30 degrees of wire, the measurement yields zero
degrees. Does that mean the phase shift in 30 degrees
of wire in a 1/2WL dipole is zero? Of course not. One
simply cannot ascertain the phase shift in a piece of
wire (or coil) by measuring the phase of the standing
wave current.

> Current is current.

On the contrary, one can look at the formula for standing wave current and see that standing wave current is NOT like traveling wave current. Traveling wave current is of the form f(z+wt) or f(z-wt) depending upon the direction of travel. Standing wave current is of the form f(z) + f(wt) so they are quite different and therefore have *different* characteristics.

As you can see from the functions, magnitude and phase are interlocked for a traveling wave. Magnitude and phase are unlocked for a standing wave. With a phasor fixed at zero degrees, how does a standing wave phasor manage to flow?

As is my custom, I am going to trim the part of your posting with which I agree.

> In every single device we would be able to build, we would never be
> able to sort reflected current from forward because current is current.

On the contrary, we do it all the time for transmission lines with a known Z0. We separate forward power from reflected power. It is trivial to take forward power in a certain Z0 feedline and convert that value of power into forward current. It is trivial to take the reflected power in that same line and convert that power into a reflected current. Here are the formulas:

|Ifor| = SQRT(Pfor/Z0) |Iref| = SQRT(Pref/Z0)

In our directional couplers, we throw away the phase when we rectify it, but we don't have to throw away the phase. We can look ahead of the diodes with an o'scope probe and actually compare the phases of the two waves.

> You have taken this argument to an absolute dead end, because you
> insist current can flow two directions at the same time at one single
> point in a system.

There you go again, "you, you, you". Everyone has requested that we cease and desist from the personal attacks. "We" means "you and me".

But it is well accepted in the distributed network model that two currents can flow in opposite directions at the same time. There's probably no other way to get standing waves and a 75m mobile bugcatcher antenna system *IS* a standing-wave antenna.

> You are demanding a measurement method that uses a device that cannot
> be built to measure something that does not exist. That is either
> humorous, sad, or frustrating. It sure isn't science.

There you go again, "you, you, you". This is not about you or me or our feelings. We can certainly measure the two currents flowing in opposite directions in a transmission line. Not having a voltage reference common is why it's hard to do in an antenna but I suspect it could be done with E-field and H-field probes

and a little superpositioning.

We are sometimes a rational species. We can perform our experiments on a transmission line with known Z0 and if we are careful, project out results on a standing wave antenna with an unknown Z0. Actually, the Z0 for a 1/2WL dipole made from #14 wire at 30 ft. from the ground is pretty well known to be about 1200 ohms.

Almost. It compares a voltage sample to a current sample, both of which have been converted into d-c voltages. These have been carefully crafted to be exactly equal d-c voltages regardless of the power level in the line.

I`m giving up on correcting line by line.

Important fact is that a reflection reverses the phase between the voltage and current produced by a wave.

So when the samples from the forward wave are siummed, their total is exactly 2x the value of either the voltage-derived sample or the current-derived sample.

When the samples from the reflected wave are summed, being equal but opposite in polarity, they add to ZERO. Calibration is so the total produces the correct value on the power scale for the wave in the forward direction.

To get the power in the reverse direction, the input and output are effectively exchanged so that the forward power indication cancels and the reverse power indication is produced by the sum of its voltage and current d-c sample outputs.

Best regards, Richard Harrison, KB5WZI

That's absolutely incorrect Richard.

If you get out the schematic of ANY directional coupler, you will see the current sampling device is in series with a voltage sampling device.

The radio frequency voltage ratios of sampling system are combined BEFORE detection.

The dc voltage level does vary with both voltage and current (power), and that is why the meter on the front of your watt meter goes up and down with power levels.

Only a phase detector levels voltages.

When you convert a sample of the RF voltage at a point to DC voltage you have a DC voltage proportional to the magnitude of the RF voltage at the point.

When you convert a sample of the RF current at the same point to DC voltage you have a DC voltage proportional to the magnitude of the RF current at the point.

You cannot use these two samples to determine generally the magnitude of the reflection coefficient (and hence VSWR), much less independent samples of the travelling waves.

No, neither a directional coupler nor a common reflectoter work as you describe Richard.

Source record: 63034

I'm trying to setup a homebrew WiFi (802.11b/g) antenna for my IBM Think Pad laptop. The coax run will be about 15" going to some home brew antennas. I don't know the name of the antenna but it can be seen at this url:

http://wireless.gumph.org/content/4/3/011-mini-wireless-antenna.html

I plan on running coax (2 lines) from the 802.11 card (internal mini PCI)
to the rear top of the LCD display. I'll terminate with connectors and attach the antennas when the laptop is open. Great plan but what about coax losses? The output of the 802.11 card is 250mw.

Most WiFi antennas use RG174 coax - I've even seen mobile antennas for WiFi with 10' runs of the stuff. Correct me if I'm wrong but wouldn't
10' of rg174 at 5 ghz be so lossy that it would defeat the purpose of the
mag mount mobile antenna?

Like I said, I only need about 15" from the output of the 802.11 card to the antennas. What coax would be good? I'm worried about losses but I also need to route the coax through the laptop and up the back of the LCD display so size (dia) matters. I guess I'm stuck with RG174 but are there better choices? What would be the losses with 15" of it into a matched load at 5ghz?

Basically, given the above conditions and with the need for both small coax and teeny connectors, what would be your recommendations?

Bob, while your model does not produce any errors with NEC 2, the
"Average Gain Test" (AGT) returns:

```
Freq.(MHz) Wavelength(m) Avg. Power Avg. Power (dB) Comments
--------------------------------------------------------------------------
146.00000 2.05340 0.78364 -1.05885
Questionable
```

All GW cards return a warning: " Seg.Len/Rad < 8. Also the pole segmentation is considered too large.

It appears that accurate modelling of such a structure in NEC 2 is not possible unless you reduce the size of your conductors.

73,

Frank

Hello Tom,

I understand that on page 6, the reference qualifies the statement in
the abstract by saying that for heights " . . . less than 15 degrees . .
. one passes to the lumped element regime . . ."

I thought Cecil was drawing examples for heights greater than 15
degrees. Have I misunderstood?

Except it is actually an incorrect concise summary.

The directional coupler adds RF voltage from a sampling across the line directly to a sampling of RF current past that point.

It is only after the voltages, one proportional to current and one proportional to voltage, are added that the resulting voltage is rectified and used to drive a meter.

The directional effect can be analyzed using wave theory or simple circuit theory. The results are the same.

2729. Balun Question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-15 00:52:46 UTC
From: Tom Ring <news0002@taring.org>
Message-ID: <4417658a$0$3760$39cecf19@news.twtelecom.net>
Source record: 63040

If one has a sealed balun, such as you would pick up at your FLARPS or a fles market, and the label has disappeared from environmental exposure, is it possible to easily determine -

1) - if you are sure it's a 1:1 whether it's voltage or current type

2) - given it's totally unknown, anything about it.

Instruments available would be a standard multimeter and an MFJ 259 or something equivalent.

I think I know the answer to 1), but 2) has me stumped. Yes, dummy loads are a start, but is there an efficient way to get all unknowns absolutely resolved.

Tom wrote, "The directional effect can be analyzed using wave theory or simple
circuit theory. The results are the same."

Of course, "the directional effect" depends completely on having the sampler calibrated to the impedance of the line into which it's inserted. Otherwise, it's just resolving "forward" and "reverse" _as_if_ the signal is in a line that has a characterisitc impedance equal to the sampler's calibration impedance.

To the extent the samples are accurate for instantaneous currents and voltages, the sampler does NOT depend on sinusoidal excitation. The result is accurate for the current and voltage that exist at each instant in time. Some directional couplers are very broadband; others are not. We made the ones in the 8753 that Tom uses to be accurate over a wide frequency range. And of course, if you don't just rectify the output, you can extract phase information from it as well as amplitude.

Cheers,
Tom

I appreciate the correction. I am weak in the area of RF instrumentation, but am learning fast. It is an area I have somehow avoided for a long time, but am getting interested in it, lately.

I would very much like to see a more complete report on the measurements you have made, in relation to this thread. I am sure I would learn from seeing that. I tried to find an operating manual or application note on the network analyzer you used, but found little that was helpful to teach me how it works, and how one applies it. It seems to have 4 signal connectors (if I am interpreting what I have found, correctly) and I can interpret your web account to mean several possible things, so I am still under a bit of a cloud, here. Your tutelage is much appreciated.

A minimum Tesla coil is 1/4WL. My 75m bugcatcher coil
mounted on my pickup as a base-loaded coil with no
whip is 1/4WL on 6.6 MHz. Going from 6.6 Mhz to 4 MHz
is only 40% shortening. I think the lumped inductor
crossover point is probably pretty far below 4 MHz.

Hi Ken

Could you use a USB connected wireless adapter?? You can dismantel some
USB wireless adapters so their antennas are available to you for attaching a
coax and even a SMA if you have the ability to work with that small stuff.

Jerry

Measure between the input terminals with an ohmmeter. A voltage balun will show a DC short, a current balun an open.

> 2) - given it's totally unknown, anything about it.

Connect the input terminals together and the output terminals together. Connect it to your antenna analyzer as a plain series load -- that is, connect the balun input terminals to the analyzer center conductor and the balun output terminals to the analyzer connector shell (or reverse the two -- it doesn't matter). Measure the impedance at frequencies of interest. You generally need a minimum of around 500 - 1000 ohms for an effective balun. The angle of the impedance doesn't matter unless you're running a lot of power, in which case a low angle (that is, a primarily resistive impedance) might result in objectionable balun heating.

You can also connect resistors of various values across the balun output and measure the input Z with your analyzer. With a 50 ohm load, you should see close to 50 ohms in over a wide frequency range. As the load gets farther from 50 ohms, you'll see more variation between the input and output Z and it'll change more rapidly with frequency. This can be corrected if necessary with a matching arrangement.

Good. It is an interesting area of electronics. If you are comfortable
with RF circuitry, RF instrumentation is only a small additional step.

> I would very much like to see a more complete report on the

This is the closest manual I could find.

http://www.home.agilent.com/cgi-bin/pub/agilent/editorial/cp_MiscEditorial.jsp?NAV_ID=-536
895237.536881282.02&LANGUAGE_CODE=eng&CONTENT_KEY=1000000108%3aepsg%3aman&ID=1000000108%3a
epsg%3aman&COUNTRY_CODE=US

For this:

http://www.home.agilent.com/USeng/nav/-536895237.536881282/pd.html

Agilent seems to obsolete things after seven years.

I have some useful equipment. Including an Impedance test set I paid
about 20K for in the 90's. It directly measures almost anything you
would every want to know.

The nice thing about having test gear is being able to build almost
anything. I have it because of work. You can do a lot with almost
nothing except a vector voltmeter and a test fixture, but the automated
measurements save me time.

Obviously a power determination must use voltage and current samples taken at the same place at the same time. We can`t use today`s voltage and yesterday`s current nor can we use the voltage over here and the current over there.

Everything happens simultaneously and at the same sampling point.

A single loop terminated in a diode is coupled to the center conductor of the coax. Its magnetic coupling produces the current sample. Its capacitive coupling produces the voltage sample. These are tweaked for identical deflection of the power meter.

Best regards, Richard Harrison, KB5WZI

There isn't any "crossover point". That point has been made several
times by different people.

There is a gradual transition over a very wide frequency range, and a
rapidly increasing change as self-resonace is approached.

You understand, Chuck, for example, my 75m bugcatcher coil, base-
mounted on my GMC pickup with no whip is 1/4WL self-resonant at
6.6 MHz, i.e. it is 90 degrees on 6.6 Mhz. By ratio and proportion,
the height on 4 MHz is 90(4/6.6) = ~54.5 degrees, 3.6 times the
transition height for passing to the lumped element regime. One
would have to divide the self-resonant frequency by 6 to get down
to the 15 degree maximum for the lumped element regime so 1.1 MHz
would be the highest frequency for which the lumped element regime
could be considered valid.

As the paper says: "Of course, the uniform current assumption
has no validity for coils operating anywhere near self-resonance."

Even the 100 uH test coil, 90 degrees self-resonant at 16 MHz,
when used on 4 MHz is 90(4/16) = ~22.5 degrees, still above
the 15 degree limit. One would have to go down to 2.7 MHz
for the lumped element regime to be valid for that 100 uH
coil and that is for an excellent coil with a Q of around 300.

I can appreciate that. I have recently gotten sucked into a wide
ranging study of ferrite rod antenna basics, and am having trouble
finding time to go to work or to bed. Almost every preconceived
notion I had about them I have been able to disprove by direct
measurement. Very educational.

So far, I am working with an RF volt meter, a signal generator or two, and an antique Boonton 160A Q meter. But I am finding lots of ways to put them to use. I would love to have a vector volt meter or vector impedance meter. A network analyzer is way beyond my budget.

>
> A mirror reflects light energy fed to it, while a light bulb takes
> electricity and turns it into light.

A reflector does not "reflect". It simply re-radiates with the correct phase and level to null energy from the other element(s) in the unwanted direction. This is why spacing and length is critical.

Try using your two element Yagi with a reflector lower in frequency. The reflector becomes a director.

Now think of a director. The director removes signal from the rear about the same as a "reflector" does. Change the length and it can become a reflector.

Now think of a mirror or a screen that is not resonant.

A mirror or screen works on a different principle. It reflects. Once it is a certain physical size, resonance does not matter. It can be 100 wavelengths across or 1 wavelength, and it still reflects. It will reflect infared or ultraviolate, and a 100 foot screen will reflect 60 meters to 10 cm all the same if the mesh is small enough.

Thinking a reflector "reflects" and a director "directs" will doom you to failure if you are trying to understand how a Yagi works.

Hi, Jerry and Ken

Pardon me for getting into this, but we would all like to know which USB adapters (and cardbus adapters currently manufactured) can be taken apart and fitted with an antenna connector. There are a number of PC card adapters that have appeared in websites showing these modifications but the units are mostly no longer manufactured. With metropolitan Wi-Fi coming in to various municipalities lately, it is becoming more desirable to put up an antenna to guarantee 100% connection when the AP is half a block away or behind a big house or dense foliage.

Thanks for your help.

Chuck

Thanks for the nice synopsis.

I would add that, because of how the physics works, the pattern that
evolves doesn't happen during the first cycle, or the first few. It
takes a while, and the more elements involved, the longer it takes.

There were some nice online "movies" (simulations) of an antenna
"building" its near and far field patterns a year or so ago. I will
have to do some googling to find them again, they were quite interesting.

> times by different people.

One of those people supporting a "crossover point" is Dr.
Corum in his IEEE peer reviewed paper at:

http://www.ttr.com/TELSIKS2001-MASTER-1.pdf (page 6)

Dr. Corum is pretty clear about 15 degrees, i.e. 4% of a
wavelength, being the "crossover point". He considers 15
degrees to 90 degrees to require a distributed network
analysis while below 15 degrees, "one passes to the lumped-
element regime ..."

The "crossover point" would be the same rule as for a
transmission line. How long does a transmission line with
reflections have to be before it is no longer valid to
consider it a lumped piece of wire. 15 degrees is 4% of
a wavelength and sounds reasonable. However, under
the right conditions, one could arrange a current node
at the halfway point of that 15 degrees of feedline thus
causing current to flow into both ends of the feeline
at the same time. 1/2 cycle later, current would be
flowing out of both ends. How would a lumped-circuit
model handle those conditions?

The "crossover point" is obviously arbitrary but if one
locates it very far above 15 degrees, according to Dr.
Corum, one risks invalid analysis results such as have
been reported here.

Cecil,

(No smiley faces this time. No trolls or tricks either.)

The assertion that there is some important difference between a standing wave and its component traveling waves has been made on a number of occasions in this thread. Indeed, that concept seems pretty central to the entire issue.

It may be worth examining the importance of this distinction further.

Basic assumptions:

* System is linear, with no diodes, saturating cores, etc.

* System is steady-state, with no startup transients.

* System is lossless, including a lack of radiation

* Superposition applies, i.e., scaling works and we can add subcomponent functions without error. The whole is precisely equal to the sum of the parts, no more and no less.

If any of these assumptions are not operative, then what follows may not be correct.

As you have stated, including references from Hecht, it is customary to mathematically show traveling waves in the form: cos (kz +/- wt)
Through straightforward addition and simple trigonometry is is seen that the standing wave corresponding to the sum of equal magnitude forward and reverse traveling waves has the form: cos (kz) * cos (wt)

The key question then becomes, what information has been lost in adding the traveling waves to form a standing wave? All of the parameters and variables are still in the standing wave equation, namely, k, z, w, t. The numerical values and definitions for these terms have not changed. One can add constant phase offsets in the traveling wave equations, but those don't really add any new information, and in any case they are not lost in converting to the standing wave format.

Are there some hidden variables that have not been considered? If so, what are they, and where do they show up in the original traveling wave equations? If not, why does the analysis and measurement of the traveling wave components give one iota more information than the analysis and measurement of the standing wave?

There is little doubt that real world conditions will violate some of the assumptions, but that does not seem to be the issue in the debate at

this time.

Again, what extra information would be gained if somehow the traveling
wave components could be measured?

Well, I'm not just building *any* WiFi setup - I researched a bit and found
on eBay what is generally agreed on to be one of the top 5 internal 802.11
cards. With up to 250mw output and external antenna, I plan on diving into
a new hobby - wardriving.

I could just buy a USB WiFi adapter and crack open the case and hack it
with an external antenna but from what I've seen, both the low output and
poor rx sensitivity seem to be quite common with these devices and that
is not what I want.

I did remember a bookmarked site which calculated the info I needed. Turns
out that my coax in question will have about 1.7 db loss at 5ghz. Not
too bad.

Still, if anyone knows of a coax that is better than RG174 while being about
the same size, please chime in with your comments!

Ken KG0WX

Hi Chuck

Although I dont have a part number for a USB wireless adapter, I can get the number from my buddy's adapter. He replaced the built in antenna the USB wireless adapter with a short coax to his Wireless antenna. I assummed the adapters are available at places like Fry's.
I am using a different approach here at home. I put a Bridge behind small satellite TV dish and suffered the loss associated with foot and a half of coax loss to the illuminator. That allows me to run CAT 5 to the computer.

I see I made a typo and typed a '+' sign in my previous equation.
Of course, it should have been a '*' sign for multiply.

> Are there some hidden variables that have not been considered?

Not a hidden variable, but there seems to be a hidden
mathematical concept, at least hidden from some individuals.

In case some might not know, 'z' is the position up and down
the wire, omega (w) is our old friend 2*pi*f, and 't' is, of
course, time.

In the traveling wave equation, cos(kz +/- wt), the position on
the wire and omega*time are added or subtracted *before* the cosine
function is taken. That means that the position on the wire and the
phase velocity are inter-related. One cannot have one without the
other. And that is indeed a characteristic of a traveling
wave. Physical position, frequency, and time all go into
making a traveling wave. It is modeled as a rotating phasor.

However, in the equation, cos(kz) * cos(wt), the physical position,
'z' is disconnected from the phase velocity, 'wt'. The standing wave
is no longer moving in the 'z' dimension. If you pick a 'z' and hold
it constant, i.e. choose a single point on the wire, the standing
wave becomes simply some constant times cos(wt). Thus at any fixed
point on the line, the standing wave is not moving - it is just
oscillating at the 'wt' rate and a current probe will certainly pick
up the H-field signal. The phase of the standing wave current is
everywhere, up and down the 1/2WL thin-wire, equal to zero. The sum
of the forward phasor and reflected phasor doesn't rotate. Its phase
doesn't change with position. Only its magnitude changes with position
and if the forward wave magnitude equals the reflected wave magnitude,
it is not flowing in the real sense that current flows. It is a
standing wave and it is just standing there.

The main thing to realize is that the standing wave equation
divorces the position of the standing wave from its phase
velocity such that the phase velocity is not active in the
'z' dimension, i.e. up and down the wire. The standing wave

current "pseudo phasor" is not rotating. The standing wave
is not going anywhere. It is not flowing along a wire or
through a coil. Measuring its phase is meaningless because
the phase is already known to be constant and unchanging from
tip to tip in a 1/2WL dipole or across a loading coil in a
mobile antenna.

Thinking that standing wave current flows from the middle of a
dipole to the ends is just a misconception. The equation for
a standing wave indicates that it doesn't flow. What is flowing
are the forward and reflected waves.

That's probably what he has in mind: using longer coils to
get the correct phase shift. He'll have to use the formulas
in the reference to make coils that will test his ideas.
I don't understand why he uses a coil at all, in that case,
since he could just as easily use a length of coiled up
transmission line to accomplish the same thing. I think he's
been trying to prove that coils, as people currently use them, are
really transmission lines that automatically shift the current
phase the correct amount to cancel antenna reactance. If
he applies his reference formulae to one of Tom's coils and it
doesn't show the correct phase shift, though, his theory is in trouble.

>
> 2) - given it's totally unknown, anything about it.
>
> Instruments available would be a standard multimeter and an MFJ 259 or
> something equivalent.

assuming its a wound balun...
attach some alligator clips to a variable resistor, and set it to around 50
ohms or so - then attach it to one side of the balun. and attach coax from
the mfj259 to the other side.
turn on the mfj and adjust the resistor for low swr (you'll have to measure
it later)
turn it off and measure the resistance you had to adjust it to.
Dividing that value by 50 will probably be the balun's impedence ratio
(4-to-1 - or whatever)
Change freqs on the MFJ and go it over again till you determine the
bandwidth.
(If you adjusted the resistor to 200 ohms and it shows SWR of 1:1, then its
a 4 to 1 balun)

Please allow me to describe the antenna I was talking about which is
"similar" to a dish for HF. It obviously is not a dish but it has the
appearance of a dish as it has no directors as it were
but multi reflectors.The reflectors tho straight are not in line but
form a parabolic shape behind a driven dipole. Using this as a
illustrative model it shows that
(a) multiple "reflectors" can be used to advantage and it some cases
can be shorter than the driven element thus illustrating that element
length does not determine reflector versus director.
And (b) it also illustrates how the primary radiated beam can be
lowered versus a yagi with the driver at the same height.
And (c) that a single reflector is not always the best choice
My intention was to describe an array that looked like a dish
physically but illustrated how multi reflectors can replace multi
directors to advantage. I apologise that I used the word "simulate"
when comparing it to a dish but as you can see I was describing what
had the "appearance" of a dish is actually an array which I used as a
illustrative model to describe or emphasise that element length,
position etc with the terms director and reflector
can mislead and it is always better to stay with the generated fields
aproach.
It was not my intention to bring true dishes into the post

I've pretty much switched completely to the Plasti-Dip stuff myself. It
is readily available in at least two colors--red and black--at Lowe's.

I used RTV, both the acetic acid and non-acetic acid varieties through
the years. After a couple of unpleasant corrosion experiences with the
acetic acid type, I began either wrapping connectors with vinyl
electrical tape or spraying with acrylic sealant and then applied the
RTV. Either way works well. I recall seeing cautions that one should
be wary of black RTV in that it could conduct. I don't know whether it
can break down but I've used the clear product.

Why don't you crunch the numbers using your reference and find out for sure? (If your reference is correct, that is. Some of the papers by academics on the web don't always give information that corresponds to reality.) You should be able to analyze your bugcatcher easily and report what you find. It sure beats sitting around drinking Ripple and feeling persecuted.

His reference formulae are for traveling waves, not standing waves.
We already know that the phase of the standing wave current on a
1/2WL thin-wire dipole varies not one degree over that entire
180 degrees. Yet we know the forward wave undergoes a 90 degree
phase shift from feedpoint to tip and the reflected wave undergoes
a 90 degree phase on the trip back to the feedpoint. Standing wave
phase is virtually unchanging and is therefore useless for trying
to determine the electrical length of a wire or a coil.

Supplementing, if I may, many fan-wire antennas are fed from the mast. (I've
climbed most of the ships in the Pacific Fleet at one time or another.)
Coax into the matching network box and port/starboard feedwires out.

The traditional design used the fan from 2-6, another antenna, maybe a cage
for 4-12 and a third, maybe a discone or trussed whip, from 10-30. These
are fed by four- or eight-channel multicouplers in Radio.

A newer design, called HFRG, for HF Radio Group, uses a 2-9 fan and maybe
twin whips from 8- 30. HFRG tolerates a 4:1 SWR ... I don't think you can
get a match of 3:1 over a wide range like 2-9 or 8-30. (In a lab, maybe.)
I Googled for AN/URC-131 and got:
http://www.rfcomm.harris.com/products/integrated-communications/anurc-131v.p
df It's mostly a Harris puff piece, but there's a little techie stuff.

I have to say "maybe" a lot because of differences between classes and even between different levels of modernization within a single ship class.

John
KD6VKW
US Navy since Jan, 1962, in many capacities.

John P. wrote, "A network analyzer is way beyond my budget."

Though I'd love for you to buy a nice new Agilent Vector Network Analyzer, I have to say that for things up through low VHF at least, the very economical project at http://users.adelphia.net/~n2pk/index.html is well worth looking at. The performance, when properly calibrated, needs no apologies, for sure. Paul is one of the Good Guys in ham radio, and not just for making this project available.

One of Tom's links probably won't work for you, but I'd highly recommend some of the ap notes you can find after a somewhat diligent search. I'm sorry to say that the search engine on the Agilent web site is a poor relative of Google, but you should be able to find these two ap notes there:

Agilent AN 1287-1: Understanding the Fundamental Principles of Vector Network Analysis

Agilent 1291-1B: 10 Hints for Making Better Network Analysis Measurements.

They are in PDF files, and I just saved a copy of each...just in case you can't find them.

A Google search on phrases like "network analysis application note" and "VNA application note" should yield some interesting things. Here's one thing I found, which has links to others: http://na.tm.agilent.com/vnahelp/appnotes.html

Finally, there is an old HP ap note on S-parameters that you should try to find. It _may_ be on the Agilent web site, but if not, a Google search will probably turn it up. Though a Vector Network Analyzer does not necessarily have to do S-parameter measurements, the 8753 is set up to do them as its fundamental measurement, and they are generally useful in making higher frequency measurements, since the standard methodology in the industry is to use S parameters to characterize both passive and active devices. If you look at network analyzers on eBay, you may see ones offered without the S-parameter test set, and you can find the S-parameter test sets offered separately; that's all fine so long as you understand what you are looking at.

Cheers,
Tom

FWIW, the "single loop terminated in a diode" that provides both magnetic and electric coupling at the same time is not the only way to make a directional coupler. It can be done with a ferrite toroid to measure the current and a capacitive voltage divider to measure the voltage; it can be done with a pair of identical RF transformers, one to monitor the voltage (connected step-down across the line) and one to monitor the current (connected step-up in series with the line). In fact, RFSim99 has a window you can access from the Tools-->Component-->Coupler pulldown menu, that will help design a directional coupler in several different ways. (Beware that the coupling they tell you for coupled lines is only for coupling sections 1/4 wave [or 3/4 or 5/4 or...] long.) Of the ones shown there, only the transformer one is broadband.

Cheers,
Tom

The physical height of my 75m bugcatcher coil is about 0.167 meters.
Dividing 0.167m by 11.4m gives the velocity factor equal to 0.015.

Your 11.4 meter value assumes a VF of zero. Multiply the 11.4 meters
by the VF of the environment and you will obtain the physical length
for something with an electrical length of 90 degrees.

To obtain an electrical 90 degrees using RG-213:

11.4m * 0.66 = 7.5m

To obtain an electrical 90 degrees using my 75m bugcatcher coil:

11.4m * 0.015 = 0.167m

Gee Cecil, how does one learn of such a "hidden mathematical concept", when it does not seem to be embodied in the formalism?

Let's try again.

Suppose the standing wave is examined to perfection. Everything that can be determined is measured without error. Now we take the superposition in reverse; specifically we divide the standing wave into forward and reverse traveling components. It would seem that we have a complete and accurate definition for the two traveling wave components. The interrelations, as you call them, between the variables and parameters are fully defined by the basic math and the carefully measured standing wave.

What else is needed to describe the traveling waves? Additional variables? Additional coefficients or parameters? Additional hidden mathematical concepts?

There seems to be a lack of understanding and appreciation for what the concepts of "linear" and "superposition" really mean. These are not just mathematical concepts. When they apply it means that the system under study is fully and completely described by ** either ** the individual functional subcomponents ** or ** the full superimposed functional component. It is not necessary to use both formats, and there is no added information by doing so.

Take a look at any of your favorite antenna references with an eye toward the treatment of standing wave antennas. I believe you will find only passing discussion of traveling waves. There will be some mention of the equivalence between the two types of waves, but little else. It is unlikely that you will find anything that says you will get more information if you take the time and trouble to analyze traveling waves.

My old Heathkit HM-15 SWR meter has a short slotted through-line
with two parallel pick up wires located about halfway between the
center conductor and the shield. A 50 ohm resistor to ground at
one end kills the voltage in that direction. A diode at the
other end rectifies the voltage in the opposite direction.
With two resistors and two diodes on opposite ends of the two
pickup wires, they separate the forward wave from the reflected
wave.

The operation of the slotted line + pickup wires seems to be
a lot like the Thruline element in a Bird but with no slug
to rotate.

Hi Bob, you are probably right about the different software standards. The NEC-2 Users Manual, p8, first paragraph, states: "Delta/a must be > 'about' 8 for errors < 1%". I guess the developers of 4nec2 considered the error for Delta/a > 6 to be acceptable.

Your model, in free space with no pole, does deviate a little from a thin wire dipole of the same length. Possibly the stub effects the pattern some.

Both of Cebik's books make excellent reading for NEC modeling, although oriented to Nittany's products. Also www.cebik.com is a good source of information.

Gene Fuller wrote:
> ... how does one learn of such a "hidden mathematical concept",
> when it does not seem to be embodied in the formalism?

The standing wave function equation, cos(kz)*cos*wt), is different
in kind and function from the traveling wave function equation,
cos (kz ï¿½ wt).

When two traveling waves are moving along the same path in opposite
directions, their two phasors are rotating in opposite directions. It
is the sum of their phase angles that is a constant number of degrees.
It is that constant phase angle that has been measured and reported
here. Kraus shows a plot of the standing wave angle for a 1/2WL thin-
wire dipole. It is zero from tip to tip. Kraus has already told us that
its value is zero degrees. For a non-thin-wire, it deviates from zero
degrees, but not by much. There's no good reason to keep measuring it
over and over. A quantity whose phase is fixed at zero degrees cannot
tell us anything about the phase shift (delay) through a coil or even
through a wire.

Given: The phase shift in the standing wave current through 1/8WL of
wire in a 1/2WL thin-wire dipole is zero degrees.

What valid technical conclusions can be drawn from that statement?
That there is no phase shift in 45 degrees of wire in a 1/2WL dipole?

> wave.

No argument. What some individuals seem to have missed are key
concepts involved in that process. In fact, that very process is
what I am presenting here.

> What else is needed to describe the traveling waves? Additional
> variables? Additional coefficients or parameters? Additional hidden
> mathematical concepts?

What else is needed is already there but unrecognized by a number of
individuals. The equations for the forward and reflected waves are
different in kind and function from the equations for the standing
wave. Assuming equal magnitudes and phases for the forward and

reflected waves, the superposition of those two phasors yields a
result that is really not a bona fide phasor because it doesn't
rotate.

One cannot use a quantity whose phasor doesn't rotate to measure
phase shifts (delays) through coils or through wires. Pardon me
for having to state the obvious.

Picture one end of the 1/2WL thin-wire dipole and set the reference
phase of the forward current at 90 degrees. This is for reference
only to make the math easy. When the forward current hits the end
of the dipole, it undergoes a 180 degree phase shift and starts
traveling in the opposite direction as the reflected current. For
ease of math, let's assume the magnitude of the forward current and
reflected current at the end of the dipole is one amp.

Here's what the standing wave current will be at points along the
dipole wire looking back toward the center. The first column is
the number of degrees back toward the center from the end of
the dipole, i.e. the end of the dipole is the zero degree reference
for 'z'. The center of the dipole is obviously 90 degrees away
from the end.

Back forward current reflected current standing wave current
0 deg 1 at 90 deg 1 at -90 deg zero
15 deg 1 at 75 deg 1 at -75 deg 0.52 at 0 deg
30 deg 1 at 60 deg 1 at -60 deg 1.00 at 0 deg
45 deg 1 at 45 deg 1 at -45 deg 1.41 at 0 deg
60 deg 1 at 30 deg 1 at -30 deg 1.73 at 0 deg
75 deg 1 at 15 deg 1 at -15 deg 1.93 at 0 deg
90 deg 1 at 0 deg 1 at 0 deg 2.00 at 0 deg

Seven points on the standing wave current curve have been produced
by superposing the forward current and reflected current. One can
observe the phase rotation of the forward and reflected waves.
Please note the phase of the standing wave current is fixed
at zero degrees. Measuring it in the real world will produce
a measurement close to zero degrees. Its phase is already known.
Measuring it multiple times over multiple years continues to
yield the same close-to-zero value. Except for proving something
already known, those measurements were a waste of time.

The above magnitudes and phases of the standing wave current are
reproduced in a graph by Kraus, "Antennas for All Applications",
3rd edition, Figure 14-2, page 464.

> There seems to be a lack of understanding and appreciation for what the

> added information by doing so.

No argument there. But the individual doing the superposition needs to understand exactly what he is doing or else he may make some conceptual mental blunders. Trying to measure the phase shift of a quantity that doesn't shift phases is one of those mental blunders.

> Take a look at any of your favorite antenna references with an eye

My only bona fide antenna references are Kraus and Balanis. Quoting:

Kraus: "A sinusoidal current distribution may be regarded as the standing wave produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along the antenna."

Balanis: "The sinusoidal current distribution of long open-ended linear antennas is a standing wave constructed by two waves of equal amplitude and 180 degree phase difference at the open-end traveling in opposite directions along its length."

Balanis: "The current and voltage distributions on open-ended wire antennas are similar to the standing wave patterns on open-ended transmission lines."

Balanis: "Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave currents ..."

> could be measured?

Hopefully, some individuals would gain enough information
that they would cease trying to use a quantity that doesn't
change phase for the measurement of phase shifts. Maybe
iteration would help.

The phase shift of standing wave current through 30 degrees
of coil or wire is close to zero degrees.

The phase shift of standing wave current through 45 degrees
of coil or wire is close to zero degrees.

The phase shift of standing wave current through 75 degrees
of coil or wire is close to zero degrees.

Measuring the phase shift of standing wave current through
a wire or a coil is pointless. One cannot use a quantity
that doesn't change phase for the measurement of phase
shifts.

Tell me a couple of things, Cecil: 1. the diameter of your bugcatcher coil, and 2. the turn to turn wire spacing. I'd like to use the information, using the formulae in your reference, to see just how long your bugcatcher coil is electrically.
Thanks,
Tom Donaly, KA6RUH

Nobody said it was resonant. The electrical length at 4 MHz
can be *estimated* from the self-resonant frequency of 16 MHz.

90 degrees at 16 MHz estimates to be approximately
90(4/16) = ~23 degrees at 4 MHz. Dr. Corum's strongly suggested
minimum electrical length for valid application of the lumped-
circuit analysis is 15 degrees.

Let's do a simple calculation to see how much error would be
had by using the lumped-circuit model in the following:

X---15 degrees of 450 ohm ladder-line---50 ohm load

The lumped-circuit model says the impedance at X is 50 ohms.

The impedance at X is really 53.5+j119

According to Dr. Corum, that's the maximum acceptable error
when using the lumped-circuit model. His standards apppear
to be lower than mine.

That just shows how poorly we sometimes understand the workings of an inductor.

The fact an inductor has self-resonance at one frequency (16MHz) does not mean we can assume it is 90 degrees at that frequency and 45 degrees at half of that frequency!!

This business of treating an inductor like a transmission line is destined to produce theories that crash and burn.

You seem to be shy of many details from your reference. VF of zero
indeed.... You can't even plug-n-chug your own referred equations.
Such are the hazards of a Xerox research method.

Hi Tom,

As you, I didn't expect to see any concrete numbers from that last
flurry of equations. I don't see how with his free mix of quarterwave
substituted as resonant to backfill an argument of a short coil
justified as a long one.

Tom's simple example, a 2 inch diameter coil of 10 inches with 100
turns seems to have buffaloed his finding the Velocity Factor or
Characteristic Impedance. And how would it compare in contrast to
Reggie's formulas? That would seem to invite discussion of results
instead, which would have collapsed this opus to a thread of three
postings.

As such, it serves only to entertain on a rainy morning (your weather
may vary - but in Seattle, never).

Cecil,

Thanks. Your quotes demonstrate my point quite nicely. There is not the slightest hint that there is any special value in treating a standing wave as a pair of traveling waves. The statements say only that it is possible. Indeed, it is clear from the quotes that the two treatments are equivalent.

Of course these authors were disadvantaged by a lack of understanding of your "hidden mathematical concepts." 8-)

Please note that when my 75m bugcatcher coil is mounted
just above my GMC pickup ground plane, it is electrically
almost four times longer than it is laying on a stack of
books in my hamshack. The coil capacitance to ground is
obviously a lot higher when mounted over a ground plane.
The ground plane reduces the VF to approximately 1/4
the value obtained in isolation.

1. The measured self-resonant frequency of the coil
mounted on my pickup is ~6.6 MHz.

2. The measured self-resonant frequency of the coil
on a mag mount on my all-metal desk is ~6.6 MHz.

3. The measured self-resonant frequency of the coil
isolated from any ground is ~24.5 MHz.

The self-resonant frequency needs to be measured in
the environment in which it is installed. That means
one needs to model the coil 3 inches above a perfect
ground plane before calculating the self-resonant
frequency, Z0, or VF. I doubt that Dr. Corum's equations
take that into account since it would seem self defeating
to operate a Tesla coil over a physically close ground
plane. But I could be wrong on that point.

The coil data is: ~6" dia, ~6.7" long, 26.5 T, seems
very close to 4 TPI. Looks to be #14 solid wire.

Source record: 63093

Here's a related question:

WHY do parasitic elements work the way they do?

Let's consider a two-element yagi with a driven element and a parasitic "reflector", ie a parasitic element longer than a half wavelength. (We could make the same arguments in reverse for a "director".)

The driven element radiates an electromagnetic field, some of which impinges on the reflector. This causes a current to flow in the reflector, and a voltage to appear across it. Since it is longer than a half wavelength, it acts inductive, and the current LAGS behind the voltage.

The reflector then radiates its own electromagnetic field in all directions, some of which heads back toward the driven element. (For simplicity, we ignore the mutual impedance effects and the new current which is induced in the driven element.)

If the fields from the reflector and driven element are to be in phase in the direction from the reflector towards the driven element, then the radiated field from the reflector must be advanced in phase by how much it lost traveling from the driven element to the reflector, plus another same amount as it travels back. So the phase of the field radiated by the reflector LEADS the phase of the driven element significantly.

Now the question is (assuming this is all right so far):
How do we explain the phase of the field radiated from the reflector, in terms of the phase of the current and voltage in the reflector?

Food for thought.

At this moment in time it seems Cecil is claiming an inductor acts like so many electrical degrees, but of course at any moment another waffle might pops out of the Texas toaster and change everything.

Let's assume we have a mobile antenna that is 25 electrical degrees tall. Now following the logic a loading coil acts like a transmission line, we have a 65-degree loading coil.

Following the same twisted logic, since the loading inductor is 65-degrees long, we should be able the move it anywhere in the antenna without changing antenna tuning.

Our 75 meter antenna should also work on 25 meters as a 3/4 wave antenna, and on 37.5 meters as a half-wave.

Of course we all know it doesn't behave anything close to this way.

Wouldn't it be nice if Cecil could show us all how to predict the resoances of an antenna based on his idea that loading inductor acts like a transmission line? Where are the design equations we can all use?

And indeed, the two treatments are equivalent for anyone who
understands both of them. The two treatments are obviously
not equivalent for someone who understands one and not the
other. It is an individual ignorance problem, not a problem
with the models.

If the standing wave analysis results are reported by an
individual to be different from the traveling wave analysis
results, what can we assume? If they are equivalent, why would
the results ever be different except for the ignorance
of the reporter?

Here is a 'yes' or 'no' technical question for everyone.
Is it possible to measure a phase shift through a wire
or coil using a signal (standing wave current) that
doesn't ever change phase?

The answer to that question is the entire crux of the
argument. If anyone answers 'yes' to that question, please
explain in detail how to accomplish that measurement feat.

> Of course these authors were disadvantaged by a lack of understanding of
> your "hidden mathematical concepts." 8-)

I thought we had agreed to stop using inuendo to try to
influence a technical argument. The mathematical concepts
are certainly NOT hidden. They are there for all to
understand and accept but are being ignored by certain
individuals.

> inductor.

There you go again, implying through inuendo that that 'we'
includes me but not you. This discussion is not about you
and me so I will make a few generalized statements.

An individual can understand perfectly how an inductor
works within the presuppositions of the lumped-circuit
model yet be completely ignorant of how an inductor
actually works in the real world in a distributed-network
environment.

The presuppositions of the lumped-circuit model cannot
be used to prove the validity of the lumped-circuit
model. The presuppositions of the lumped-circuit model
are invalid for many distributed-network environments.

This is a technical subject so I will ask a technical
question:

How is it possible to use a signal (standing wave current)
that is known not to change phase, to measure the phase delay
through a wire or coil?

Kraus provides a graph of that unchanging phase in Figure
14-2 of "Antennas for All Applications", 3rd edition.

> The fact an inductor has self-resonance at one frequency (16MHz) does
> not mean we can assume it is 90 degrees at that frequency and 45
> degrees at half of that frequency!!

It certainly means we can make those assumptions within some
estimated degree of accuracy because they agree with the laws
of physics which don't change just because some individual
rejects them. Helicals, in general, obey the transmission line
laws of physics. They have relatively constant values of L, C,
R, and G over a certain range of frequencies. They exhibit the
characteristics of Z0 and VF. They do NOT exhibit the
presuppositions of the lumped-circuit model.

> This business of treating an inductor like a transmission line is
> destined to produce theories that crash and burn.

Inductors have been treated like transmission lines for the
better part of a century by engineers using the distributed

network model. Since the distributed network model is a
superset of the lumped-circuit model, why would they ever
crash and burn?

There is no "standing wave current". There is only current.
Current can't stand.

Phase difference can be measured in a system that has standing waves,
just as it can in one without standing waves.

> The answer to that question is the entire crux of the
> argument. If anyone answers 'yes' to that question, please
> explain in detail how to accomplish that measurement feat.

Any number of ways, if we disallow the impossible situiation where you
seem to think we can have current "standing still". Direct measurement
methods abound.

First Cecil says:
> I thought we had agreed to stop using inuendo to try to
> influence a technical argument. The mathematical concepts
> are certainly NOT hidden.

Then Cecil does the opposite of what he asks Gene to do:
>They are there for all to
> understand and accept but are being ignored by certain

That's not food for thought. That's emotional gut feelings. I
thought we agreed to cease and desist from ad hominem attacks?

> Let's assume we have a mobile antenna that is 25 electrical degrees
> tall. Now following the logic a loading coil acts like a transmission
> line, we have a 65-degree loading coil.

False assumption! The phase delay through the coil is what it
is and we don't know exactly what it is. We do know it is not what
has been measured and reported using a signal source (standing wave
current) that doesn't ever change phase.

Our present choice is between a reported measurement that is
100% flawed, in the absolute sense of the word, and an estimate
with unknown accuracy based on the laws of physics. Given those
two, and only two, present choices, which choice should one make?

Please see the end of this posting for a description of the
logical diversion that is taking place here.

The phase delay through the coil is what it is and we don't know
exactly what it is. We do know it is not zero as the standing wave
current phase shift measurement would predict.

Let me focus the subject of the argument back upon the actual
subject of the argument and try to avoid diversions into the
unknown, like the above.

How does one measure the phase delay through a coil or wire
using a signal with forever unchanging phase? All of the phase
delay experiments so far have used the above flawed method.
So far, we only have experimental measurements that are flawed
except for the self-resonant experiments.

Which is preferred? The results from experiments known to
be 100% flawed or estimates with unknown accuracy based on
the laws of physics? Those are presently our only two choices.

> Following the same twisted logic, since the loading inductor is
> 65-degrees long, we should be able the move it anywhere in the antenna

> without changing antenna tuning.

False assumption! The superposition of all four of the
forward and reflected waves is much more complicated than that.

> Our 75 meter antenna should also work on 25 meters as a 3/4 wave
> antenna, and on 37.5 meters as a half-wave.

It's not as simple as that but I have the EZNEC current
distribution patterns that indicate something akin to
that indeed does develop. Give me a few hours and I
will post those results.

> Where are the design equations we can all use?

Asked and answered but not sure of the accuracy applied
to 75m bugcatcher loading coils. Someone is working on
that. Please stand by.

The logical diversion that is happening here goes like this:

Person A says: "The moon is 10,000 miles from the earth.

Person B says: "That can't be true."

Person A says: "How far do you say the moon is from the earth?"

Person B says: "I don't know, but I do know it is not 10,000
miles."

Person A says: "Well, if you don't know and can't give me the
correct answer, I am right and you are wrong. The moon is
10,000 miles from the earth."

Does an absolutely false answer beat ignorance?

Addressed and proven to be a false statement. cos(kz)*cos(wt)
proves it is standing and not flowing.

> Phase difference can be measured in a system that has standing waves,
> just as it can in one without standing waves.

Addressed and proven to be a false statement. A signal
with unchanging phase cannot be used to measure the
phase delay through a wire or coil.

> Any number of ways, if we disallow the impossible situiation where you
> seem to think we can have current "standing still".

Please take a look at the equation for standing wave
current. It proves that the standing wave current is
standing still, just oscillating in place at any point
on the wire.

> . . .

This test works only with a current balun. If done with a voltage balun, the impedance should be very low.

Although there are ways to test for the proper functioning of a voltage balun, that is, to test for the voltages at the output terminals being equal and opposite with respect to the "cold" side of the input, they don't tell you how effective it'll be in stopping common mode currents on feedlines. In fact, certain imperfections might improve the performance of a voltage balun in that application. I don't recommend using a voltage balun for feeding antennas for the reasons I gave in http://eznec.com/Amateur/Articles/Baluns.pdf.

I apologize for the error. Thanks very much to Owen Duffy for pointing it out to me.

You also need to ignore the fields from all other elements if present. They can have a major impact on the overall field to the rear which the reflector must attempt to cancel.

> If the fields from the reflector and driven element are to be in phase
> in the direction from the reflector towards the driven element, then the
> radiated field from the reflector must be advanced in phase by how much
> it lost traveling from the driven element to the reflector, plus another
> same amount as it travels back. So the phase of the field radiated by
> the reflector LEADS the phase of the driven element significantly.

But the purpose of the reflector isn't to make a field which reinforces the driven element's field in the forward direction, but to make a field which cancels it in the reverse direction. For this to happen most effectively, the phase lag of the reflector current (relative to the driven element current) and the distance between reflector and driven element should add to 180 degrees. In practice, both the phase and magnitude of the current induced in the reflector change with element length. And in general, the farther you get from self-resonance, the smaller induced current. So as you adjust the element length, by the time you reach the optimum phase angle of induced current, its magnitude is too small for good cancellation. A compromise is inevitably reached, resulting in an acceptable but far from perfect front/back ratio.

> Now the question is (assuming this is all right so far):
> How do we explain the phase of the field radiated from the reflector, in
> terms of the phase of the current and voltage in the reflector?

The magnitude and phase of the field are directly related to the magnitude and phase of the current. The incremental longitudinal voltage in the element can be ignored in calculation of fields. While it's possible to base the field calculation on the longitudinal voltage rather than the current, I don't believe I've ever seen this done.

I do believe that Tom is echoing what Terman is stating. Look again at
I totally disagree with the majority of this posting which
misrepresents what Terman actually said
into a self serving statement to give cover to an earlier misstatement.

Terman's statement
. He states.....the parrasitic antenna acts as a "director"
He does not say it is a director and puts it into quotation purely that
is what others call it.
If he felt that it was self explanable he would have stated that it was
a director without the need for quotation marks and prefixes the term
with the word "acts" for clarification instead of the word "is" He then
follows on with his description that further explanion to emphasis the
need to place the term inside quotationas by adding his reasons
...."and tends to concentrate the radiated field in its direction"
Note he states "tends" rather than the word "directs "because as he
stated earlier
"it acts...." and not "is" and tjhen goes on to add the coup de gras by
stating what it dioes do......
"tends to concentrate the radiated field in its direction".
I view that asa very precise statement in describing what some call a
director as actually being a field with a tendency...e.t.c.
Frankly it reiterates what Tom said where one can be doomed if it not
described correctly
and it would appear that Terman had the term "director" very much in
mind when he described what others termed as a director. He certainly
was an amazing man who saw from the beginning
the need to refrain from the word "direct" or "director" as the field
generated does not warrent such an absolute word. This may appear to be
semantics as far as you may be concerned but the above analysis of what
he actually said provides a confirmation of what others were saying.
I would agreee howver with a small point that you reffered to and that
was regarding a fool who argues with Termam as one must first
understand what one actually read and convey the message to the brain
where the emphasis is to confirm what one wanted to read'

Probably, since it appears you are the only one finding fault with them.

It appears you have painted yourself into a corner by trying o apply a paper about Tesla coils that specifically states it applies only to inductors at self-resonance to inductors operating away from self-resonance.

For example, if you look at this time-delay plot:

http://www.w8ji.com/inductor_current_time_delay.htm

you'll see time delay is essentially flat except near the 16MHz self-resonant frequency and a higher-frequency resonance at 26 MHz.

If I coupled that inductor to a oscillator like a Telsa coil has, it would indeed oscillate near the frequency where the inductor has considerable time delay. That time delay is largely because the inductor looks like a combination of shunt C and series L, and is indeed in mode similar to what we find in a transmission line. It is a narrow bandwidth effect because the resonance is high-Q. It does not surprise me at all.

2805. Element correction for through beem Yagi elements

Newsgroup: rec.radio.amateur.antenna
Date: 2006-03-15 22:17:03 UTC
From: David <dhuisman@bigpond.net.au>
Message-ID: <zn0Sf.7506$dy4.5138@news-server.bigpond.net.au>
Source record: 63116

Hi,

I am in the process of building a 4-Element Yagi to operate at 915 MHz.

The design is as follows...
Element Length Distance from REFL
REFL 159mm 0mm
DE 146mm 40mm
D1 139mm 90mm
D2 132mm 155mm

Boom is 12.8mm OD square aluminium (1.6mm wall thickness)
Elements are 6mm solid aluminium rod.

The design was assuming that the elements were to be insulated from the boom but I am having trouble making small insulators to hold these in place.
It would be simpler for construction if I could simply drill through the beam and weld the rods in place or connect via a screw through the centre of the beam.

The correction factor formula I have found seems to be for insulated through-beam elements.

Q: Is there a correction factor I can apply to enable me to construct the antenna in this manner ?

Q: Does the Driven element need to be in the same plane as the other elements or can it be out of alignment (ie. If I use a small plastic enclosure to house the balun and make connection to the driven elements, the elements will not be in the middle of the beam but rather 5mm or so above the beam).

Q: Is there an alternate design I could use that would be simpler to construct. (I am looking for around 7dB gain at low angle of radiation - point to point communications link). Feedline is 50 Ohm coaxial cable, power is less than 1 Watt.

Hope I have given enough info to evoke some constructive advice, Thanks in advance for your help

Regards

David

My testing results have been reported. Here are the results
of the VF calculation for my 75m bugcatcher coil.

The test for physical structure is met. The paper asserts
that the expression gives acceptable results with errors
less than 10%.

The VF of my 75m bugcatcher coil calculates out to be
VF = 0.0175 at 6.6 MHz where it measured to be self-
resonant. That self-resonant measurement included
a length of coax and a one foot bottom section so the
actual self-resonant frequency will be somewhat higher
than I measured. I could probably make a calculation
to adjust for the coax and bottom section.

The VF calculated directly from the too-low self-
resonant frequency was 0.015 which is 14% different
from Dr. Corum's equation. Given the uncertainly in
the exact self-resonant frequency in my measurements,
that's pretty reasonable. Ballpark is all we need
to understand the concepts.

Working backward, Dr. Corum's VF would make the
coil self-resonant at 7.7 MHz. There's probably
enough slop in my measurement configuration to
account for the 1.1 MHz difference.

As the wavelength is fairly low, I suggest you build a 6 * 1/4 wave antenna array and mount it on a roofrack. You can easily build a direction finder by phaseshifting the array with a pack of pin diodes.

This method is widely used for tracking vehicles.

Directivity... 868MHz is still a long wavelength for any exotic and directive antennas. But why not try building a loop yagi in a plastic tube. Use PCB FR4 with plastic foam as spacer between the radials.

But still, a 4 or 6 antenna array on a roofrack seems to be enough to catch stolen vehicles in the UK...

Cheers

Dan / M0DFI

Cecil, W5DXP wrote:
"How is it possible to use a signal (standing wave current) that is known not to change phase, to measure the phase delay through a wire or coil?"

Ignore it.

Lissajous figures result from applying signals to the vertical and horizontal deflection circuits of an oscilloscope simultaneously. Phase difference between signals of the same frequency make a distinctive pattern.

One can use coax lines with identical delays to couple the inputs with phase sampling loops. Take samples of the currents at the two points where the phase difference would be known. Amplitudes can be adjusted for a suitable pattern. It will be destinctive.
